A few large doses of quinine are almost invariably followed by a disappearance from the blood of the various amœboid forms. The crescentic bodies remain unchanged after quinine, but commonly show a diminution in number as the health improves under the treatment proper for chronic paludism.

These apparent results of treatment followed in my cases as in those of most other observers. The organism has not yet been discovered except in human blood and organs. It has never been isolated. It has never been cultivated outside the body.

Inoculative experiments on human beings are almost uniformly successful. Intravenous injection of malarial blood into a healthy individual is followed by typical intermittent fever, with the appearance in the blood of the second person of the various forms of the organism described. These experiments have been made by Gerhardt, in Germany, and by Marchiafava and Celli and other Italians.

Subcutaneous injections have been unsuccessful.

The few inoculative experiments that have been made upon monkeys have been unsuccessful.

As regards the name of the organism: The term plasmodium has been improperly used in this connection. This name has long been applied to a segregation stage of some of the mycetozoa, and so means, not a particular organism, but a stage of development common to many different organisms. Moreover, so far as we know, the malarial germ has no plasmodium stage.

It is much better, then, in designating the malarial organism, to use the term hæmatozoon of malaria, as suggested by Laveran, which commits us to no definite classification.

Morro injected into the peritoneal cavity of pigeons and chickens blood taken from the carotid of a dog. After two or three days he killed the former, and found in their abdominal cavities a fluid, the remains of the injected blood. This contained some red blood-corpuscles of the bird and some of those injected from the dog. The latter, he claims, showed appearances identical with those described as the hæmatozoon of malaria. Morro argues from this that the so-called hæmatozoon is not an independent organism, but merely a metamorphosis of the protoplasm of red blood-cells. Marchiafava and Celli have repeated Morro's experiments with negative results. Maraghano studied the behavior of healthy human red blood-cells when subjected to various influences. He kept for some time slides of blood the evaporation of serum from which was prevented. Other slides he subjected to pressure, others to heat. He says that under these circumstances he obtained in the red corpuscles amœboid bodies and segmenting bodies identical in appearance with those described as the organism of malaria. In blood impoverished from any cause he finds these appearances more pronounced. He does not state whether he has or has not himself studied malarial blood. I have repeated his experiments with healthy and impoverished red blood-cells, and have seen appearances which correspond fairly closely with what he has described. But in no case have I seen anything bearing close enough resemblance to the so-called hæmatozoon of malaria to justify the belief that they are identical. Klebs states that Rosenstein found in the blood in typhoid fever appearances similar to the so-called malarial organism; that Dujardin found them also in healthy blood, when evaporation of serum was for a time hindered; that Hoffmann saw such appearances in pernicious anæmia.

Pfeiffer claims to have found similar phenomena in the blood in scarlet fever, mumps, and in vaccination.

It has been suggested, too, by others that perhaps these appearances may mean merely a retrograde change in the red cells, and may accompany any of the diseases to which marked organic blood-changes belong.

As a contribution toward the settlement of this point, I have undertaken the examination of the blood in a series of cases of other diseases where a malarial element might fairly be excluded. In every case I have used either a one-eighteenth or one-twelfth oil-immersion objective and the same precautions as in the examination of malarial blood. The cases examined were 76 in number, and were as follows: Chronic phthisis, 11; pernicious anæmia, 3; chlorosis, 14; leucocythæmia, 3; jaundice, 3; cancerous cachexia, 3; chronic lead-poisoning, 1; typhoid fever, 10; pneumonia, 4; diabetes mellitus, 2; anæmia from cardiac disease, 2; acute anæmia following hemorrhage, 4; acute articular rheumatism, 5; cirrhosis of liver, 1; septic fever, 2; chronic Bright's disease, 5; scarlet fever, 3.

In the above cases I found in the blood no appearances that could be confounded with those in malarial blood by one accustomed to examine the latter. There were in the red cells only those changes usually found in blood impoverished from any cause.

As regards the classification of the organism, we place it in the animal kingdom—morphologically, because it is at no time enclosed in a cell-wall of cellulose; physiologically, because it seems incapable of making its protein from simpler substances. It seems at all times to be unicellular, so we call it a protozoon.

Further positive classification is at present unsafe. It seems, however, from its general characteristics, to belong among the flagellated infusoria. In connection with the hæmatozoon of malaria the consideration of the other parasitic protozoa is of interest. The study of these has of late been neglected, and the difficulties in the way of investigation, and especially of cultivation, of these organisms, have put rather narrow limits to our knowledge of them. Cartulis has recently found, in the stools of Egyptian dysentery and in pus from abscesses of the liver in cases of dysentery, large amœbæ which, he believes, have a causative relation to the disease. He has found them in every case of the dysentery, and never under other conditions. He has not worked out their life-history. His work has not been repeated by others.

Deichler has described protozoa in the expectoration of persons with whooping-cough. Pfeiffer and Loeff have very lately described a most interesting series of amœboid organisms, protozoa, existing in the contents of small-pox, varicella, and vaccinia pustules. But the parasitic protozoa of the blood bear an even closer relation to the malaria question.

A peculiar organism has long been known in the blood of many frogs. It was supposed by Gaulé to be merely a metamorphosis of the protoplasm of the red cells. It is often called "Gaulé's Wurmchen." Ray Lankester and others have proved that it is an independent organism—a protozoon. Part of its life is spent in the interior of a red blood-corpuscle.

Wittich has found in the blood of moles protozoa resembling closely those in malarial disease in man.

Marchiafava and Celli, examining the blood of frogs living in ponds about Rome, saw hæmatozoa very like those in malaria. In one case they found a flagellated organism which lost its flagella, these latter then going on to lead an independent existence.

Mitrophanow and Danilewsky find similar flagellated protozoa in the blood of fishes, especially the carp and mudfish; also in various other lower animals—frogs, turtles, lizards, and others.

Lewis and Crookshank, in India and in London, find similar organisms in the blood of apparently healthy rats.

It is interesting to notice that in the above list of animals, most are more or less continuously subjected to the influences and environment that in human beings are popularly supposed to give rise to malarial disease.

The above-mentioned parasites are usually called physiological hæmatozoa, since the animals serving as hosts seem healthy. It is very possible, though, that they may be the cause of diseases on the part of the host, clinical evidence of which we are unable to discover. The question whether certain fish, lizards, and birds are perfectly healthy or not is one difficult or impossible to settle.

The only apparently pathogenic protozoon that has been studied in the lower animals is that of "surra." Surra is a disease occurring in India in horses, mules, and camels. It has a distinctly intermittent character, and is accompanied by high fever, jaundice, and prostration. It is commonly fatal. In the blood of the diseased animals, Evans, Steele, and Crookshank have uniformly found a flagellated protozoon which seems to be polymorphic. The organism disappears from the blood during the intermission, to reappear again during the paroxysm.

The intravenous injection of blood from a diseased into a healthy animal is followed by the disease in typical form, and by the appearance of the hæmatozoa in the blood of the second animal. The organisms are more numerous in severe than in mild cases. They are very like those found in the blood of apparently healthy rats. They have not been cultivated outside the body.

Many of the lower fresh-water plants are infested by parasites which show striking points of similarity to the hæmatozoa of malaria. These are actively moving flagellated bodies which find their way into a vegetable cell. The body loses its flagellum and becomes amœboid. It lives at the expense of the cell it occupies, increases in size, and stores up within itself granules of brownish-black pigment which are changed chlorophyl.

Having completed its amœboid stage, it becomes encysted. The pigment-granules are gradually massed at the centre, and segmentation of the peripheral protoplasm takes place. The segments are spores, usually swarm spores, which are set free and again begin the same life-history.

These organisms were well studied by De Bary and Zopt long before Laveran's first work on the malarial organism was published. They are classed among the mycetozoa or myxomycetes. Each parasite is, as a rule, peculiar to some one plant, usually one of the fresh-water algæ.

The points of marked similarity between the mycetozoa and the hæmatozoa of malaria suggest a possible genetic connection between them, and that the malarial organism may exist outside the body as a parasite of some plant.

If malarial disease is caused by a micro-organism, we must assume that it is capable of indefinite life and multiplication outside the body. Only this supposition would explain the phenomena of intermittent fever. Chlorophyl seems to stand in closer relation to hæmoglobin than any other substance found in the inorganic and plant world.

It seems possible, then, that the malarial hæmatozoon may be also a plant parasite, and that the distribution of malarial fevers may depend upon botanical conditions, or the presence in a given locality of a plant capable of serving as host for the organism.

In conclusion, then, we may state as facts:

1. The presence of the phenomena grouped under the name hæmatozoon of malaria in the blood of persons suffering from malarial disease.
2. The presence of crescentic bodies, only in chronic cases.
3. The presence of the segmenting forms only immediately before and during the chill.
4. The disappearance of all but the crescentic forms after the administration of large doses of quinine.
5. The possibility of transferring malarial disease from person to person by intravenous injection of malarial blood.

But we must at present recognize as hypothetical though probable:

1. An etiological relation between the appearances described in the blood and the disease itself.
2. The absence of these appearances from the blood in all other conditions.
3. The assumption that the bodies described are one and the same organism.
4. The assumption that any of the forms excepting the flagellated bodies are independent organisms.

Finally, I wish to express my thanks to Dr. Francis Delafield and Dr. William H. Draper, and to the house staff of Roosevelt Hospital, for their kindness in allowing me access to the cases in the wards of the Roosevelt Hospital, and to Dr. Councilman, of Baltimore, for many valuable suggestions in regard to the study of this subject.

THE ACTUAL CAUSE OF DEATH IN PHTHISIS.—Under the title of "A Contribution toward the Etiology of Phthisis," Dr. R. W. Philip publishes the results of a study of this subject, more particularly in so far as it relates to the *modus moriendi* in this disease. His conclusions are as follows (*The British Medical Journal*, January 28, 1888): 1. In view of the work of Koch, it is impossible to avoid admitting that a casual relationship exists between the tubercle bacillus and the phthisical process. 2. The mere predication of this relationship is not sufficient in explanation of the clinical facts and the generally fatal termination of such cases. 3. The usually received explanations of the *modus moriendi* in phthisis are insufficient. 4. It appears probable that the lethal influence of the bacillus is due to the production thereby of certain poisonous products. 5. Clinical and experimental evidence appears to indicate that the morbid secretions from the respiratory surfaces afford a good medium for the growth of the tubercle bacillus, and, presumably, for the elaboration of such products. 6. Such a product is separable from the carefully selected and prepared sputum. 7. This product is possessed of well-marked physiological properties, being eminently toxic to frogs, mice, and other animals. 8. The toxic properties of the product are, speaking generally, depressant. 9. More particularly they include a marked depressant influence on the heart. 10. This depressant influence seems to be exerted through the medium of the cardic-inhibitory mechanism. 11. The toxic action of the product is more or less completely opposed by atropine. 12. The amount of the product which may be separated appears to bear a distinct relation to the abundance of the bacillar elements present. 13. Absorption of the poisonous product most probably occurs by way of the lymphatic circulation.

NOTE ON THE SURGERY OF THE ENLARGED PROSTATE.

By WILLIAM T. BELFIELD, M.D.,

SURGEON TO THE COOK COUNTY HOSPITAL, CHICAGO.

EXPLORATION of the bladder in fifteen cases of severe cystitis dependent upon prostatic enlargement has confirmed the teaching of numerous autopsies, namely, that the severest vesical disturbance is induced, not by diffuse prostatic enlargement—which may be detected by rectal examination—but by localized prostatic outgrowths, which are not discoverable per rectum nor, indeed, in any way other than by the finger in the bladder. These tumors—which, like uterine fibroids, are true myomata—may be associated with much or little diffuse hypertrophy; while often originating in the substance of the gland, they are frequently found, when the cystitis has become severe, protruding at or near the urethro-vesical orifice. In this locality even a small tumor, associated with but little diffuse hypertrophy, may seriously impede the exit of urine and entail the usual cystitis, calculus formation, etc.

Among my fifteen cases such intravesical tumors were found in eight—three times as a single myoma, or so-called "middle lobe," and in five as a more or less complete ring around the vesical orifice. In five of the remaining cases the growths were chiefly intraprostatic; in the two others there was found diffuse hypertrophy, with encysted calculi.

In eight of the fifteen cases, therefore, the prostatic obstructions were, at least from the anatomical stand-point, removable. These obstacles are accessible to the surgeon by two routes—perineal and suprapubic incision.[1] That the suprapubic renders the bladder more accessible for manipulation than the perineal incision is apparent to all who have approached it through both; the inferiority of the latter is extreme when the prostate is enlarged—a fact impressed upon me in many cases, including two where I removed with the cautery portions of prostatic outgrowths through a perineal incision.[2]

In June, 1886, I undertook suprapubic prostatectomy, but after the extraction of two large calculi was forced by the patient's condition to abandon the operation;[3] in October of the same year I executed the plan, removing a "middle lobe" of the size and shape of a small almond.[4] The patient, seventy-three years of age, who for a year had been dependent upon his catheter, has urinated freely since. In a second case I repeated the operation, removing a mass as large as a bean. Mr. McGill recently reported to the London Clinical Society three cases in which the same operation was performed with entire success.[5]

It would seem, therefore, that these cases of severe and protracted cystitis from prostatic enlargement should no longer be universally permitted to suffer without an attempt at operative relief; that in suitable cases, after failure of other means, a suprapubic exploration of the bladder should be made. In a certain percentage of cases the obstacle to urination will be found as a projecting prostatic growth which can be removed with scissors or cautery. The latter minimizes hemorrhage and the chance of septic infection, the bladder-wall being meanwhile protected by a thin sheet of asbestos.

When no removable intravesical tumors are found, the bladder is at least drained and rested, and the prostatic œdema, usual in advanced cases, subsides; in cases by no means rare, calculi undetected by the sound, because encysted or ensconced below the prostate, will be found.

---

[1] Operations on the prostate through the urethra, such as Mercier's and Bottini's, were merely tentative, hap-hazard procedures. The surgeon works in the dark, without definite knowledge of the obstacle to be overcome, or of the damage done by his instrument; moreover, two most important advantages of cystotomy—repose for the bladder and a search for hidden calculi—are not obtained.

[3] THE MEDICAL RECORD, August 21, 1886.

[4] Journal Am. Med. Assn., March 12, 1887.

[5] Brit. Med. Jour., November 19, 1887.

In cases where the prostatic urethra is found to be hopelessly distorted and occluded, a permanent opening above the pubes can be maintained and fitted with a tube, dispensing with the painful and futile employment of the catheter. This proceeding, already successfully employed in a few cases, has, I think, a large field of usefulness in patients too feeble to endure a more radical operation or even the anæsthetic necessary thereto. A little chloroform—possibly even cocaine locally—produces sufficient anæsthesia for the slight incision required for the insertion of a finger and a catheter into the bladder.

In cases of prostatic enlargement where the cystitis is still slight, and operative interference seems therefore unjustifiable, the use of an intense galvanic current, after Apostoli's method with uterine fibroids, is worthy of investigation. During the past year I have used it in four cases, and found, contrary to my expectation, that a current of fifty to ninety milliampères, through the prostate from bladder to rectum or perineum, is well borne. Two of the four cases have greatly improved; yet, as such patients often enjoy comparative comfort for considerable intervals without local treatment, it is by no means certain that the improvement is due to the current.

A CASE OF HYSTERICAL COMA.

By ELIZABETH L. PECK, M.D.,

SOUTH HADLEY, MASS.

Miss C——, aged twenty, returned to school after the holidays, on Tuesday, January 3d. She suffered from a headache with some nausea during the journey, and the nausea persisted. On Thursday evening she complained of her feet and legs feeling queer, and that she could not walk straight, but as she had been in bed all day her roommate thought little of it. The next morning, however, she seemed very sleepy and would not answer questions. I saw her for the first time at 9 A.M., Friday, and judged the condition an hysterical one. As she was vomiting all food taken, I ordered her to take milk and lime-water in small doses, but the vomiting still continued, and the stupor of the patient increased. Though naturally somewhat fastidious, she seemed not to mind the condition of her own or her bedclothing, and could be roused to move herself only very little, though there were no evidences of paralysis.

This condition lasted from Friday until Wednesday, with only occasional slight indications of consciousness. During this time the temperature was normal, as were also the pulse and respiration, most of the time. Liquid food was taken at short intervals, as the vomiting ceased after the administration of a few doses of dilute hydrocyanic acid; yet swallowing was difficult, the food being retained for some minutes in the mouth and often partially ejected. The urine was passed involuntarily and frequently; the bowels, however, were moved only by enemata, though the sphincter was somewhat relaxed. During sleep the breathing was much of the time stertorous.

One thing at this time was of interest, as a point in diagnosis—a small phial containing some homœopathic remedy was found by the young lady's room-mate, which on Thursday had been nearly full, and on Friday morning was quite empty. Her symptoms were so strikingly like those of some narcotic poisons that, until I had ascertained the nature of the drug, or, in fact, until time had set at rest this question, the state of affairs was puzzling; the more so that on Sunday morning there were, for a short time, indications of heart-failure, although up to this time the pulse and respiration had been fair. This condition was temporary. There was some loss of reflex excitability, the conjunctivæ being markedly yet unequally insensitive, and the response to external stimulation slow and incomplete.

On Sunday afternoon the patient was seen by Dr. Cox, of Holyoke, Mass., who agreed with me that the case was hysterical in nature. This state of profound stupor passed away very gradually, and nothing seemed to possess much power to rouse the patient, except the application of heated iron to the spine. The effects of this treatment would last several hours; she would sit up, perhaps say a few words, but at length relapse into her accustomed lethargy.

During the second week of her illness a rather scanty menstrual discharge occurred. All the time of her illness she made no objection to taking asafœtida—would, indeed, take medicine more readily than food. Her treatment was tonic, as depressing measures seemed at no time indicated. After the stupor had passed away, she was some of the time very restless and wilful. Four weeks from the beginning of the attack the patient was able to leave for her home, about one hundred miles distant, physically in fair condition; her mental balance was not yet fully recovered, and she would become incoherent after talking a few minutes.

The case seemed a peculiar one from the absence of any adequate exciting cause for so profound a disturbance of cerebral functions. She had not been well during the fall term, and I had advised her to remain out of school for a time on account of persistent neuralgia accompanying an anæmic condition, and her return in the winter term was allowed with some hesitation on account of her health. However, she had seemed better during vacation, and she had probably overdrawn the stock of her already exhausted energies in the excitement of a gay holiday season. This, at least, seems the only rational cause to be assigned for the attack. She had never been a hard student, and had always been fond of out-of-door sports. Her muscular development was better than that of the average girl.

A PECULIAR CASE OF FOREIGN BODIES IN THE ALIMENTARY CANAL.

Dr. J. B. Kell, of Delphos, O., writes: "Apropos of Dr. Jones' article on foreign bodies, published in The Medical Record of February 18th, I report below an interesting and almost similar case: Mr. P—— called on me a few weeks ago and stated that his two-year-old boy had got into his mother's work-box, evidently looking for something to eat; at any rate, he detached from the card and swallowed twenty-three small shirt-buttons, probably one-third of an inch in diameter. His father stated that they were about to administer to him a dose of castor-oil, when he concluded it would first be better to consult their physician. Of course I countermanded the oil and fed the child on corn-bread alone for a period of two days, at the end of which time the buttons were passed, lying in the centre of a large, well-rounded fecal mass. Counting them carefully, we found just twenty-three—the exact number he had swallowed."

For Irritable Bladder.—Dr. W. P. Chunn writes to the *Maryland Medical Journal*, January 28, 1888, that the following prescription has been found to allay incessant desire to urinate and irritable bladder, when due to phosphatic deposits in the urine:

℞.	Acidi benzoici	ʒ ij.
	Boracis	ʒ iij.
	Aquæ	℥ xij.

M. Sig.—Tablespoonful three times a day.

This mixture has, upon two occasions, acted so efficiently in what was thought to be cystitis that cystotomy was dispensed with.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, March 10, 1888.

THE STATE CARE OF THE INSANE.

THAT it should be necessary to raise the medical voice in favor of "State care for pauper insane" seems hardly possible.

The opposition to and the false arguments which have been raised against the bill now pending before the Legislature, entitled "An act in relation to the care and custody of the pauper and indigent insane in the counties of this State, excepting New York, Kings, and Monroe," prove, however, the necessity for a note of "no uncertain sound" from our profession in favor of State *versus* County care.

The policy of our State from 1855 to the passage of the law, in 1871, giving power of exemption from the provisions of the Willard Asylum Act to the State Board of Charities, has been unswervingly that the "poor insane are the wards of the State."

The necessities leading up to this policy are well known to those who have made any study of the history of this afflicted class.

The horrors of the so-called care they received in poorhouses and prisons seem almost incredible, viewed with the light of our present knowledge and humanity; and the question must now be asked, most seriously, Shall this State desert her high standard, and drift backward into any of the evils from which she has been trying to free herself?

The struggle begun by the County Superintendents of the Poor crying to the State for help, in 1855, resulted in the passage of the Willard Asylum Act, in 1865, by the provisions of which all chronic insane were to be sent to State asylums.

Since power of exemption from this act was given to the State Board of Charities, in 1871, seventeen counties have been relieved of its action, and we may safely affirm that the number of counties seeking exemption is, and will continue to be, rapidly on the increase.

Appropriations are now being asked for in many counties; other counties are building asylums. Let this go on, and the time will soon have passed when it will be possible to check the evil.

In face of this danger, let us consider what are the advantages of State institutions; what is the exact state of things in the exempted counties; and what is the remedy.

Where, in the course of our medical experience, can we find patients who require early diagnosis and treatment, careful classification, and constant watchfulness more positively than the insane. Add to this the moral treatment, which is ever growing in its importance, and how imperative does it become to have at hand all those resources which a fully equipped institution alone possesses.

This is what State care means: An asylum in the hands of a Medical Superintendent who is an alienist, aided by intelligent assistants, careful, trained nurses, and all that science can provide, with every facility for occupation and diversion, according to the demands of each patient. Over all this the ever-watchful care of a Board of Trustees, entirely removed from politics, appointed by the Governor.

Of the present trustees of Willard, consisting of eight members, four have been in office since the founding of the asylum.

Now, we must remember that in the County system the Superintendent of the Poor and the Board of Supervisors stand for what the trustees of a State institution represent.

They are elected annually, and to their political power only they owe their positions. In this short term they are supposed to acquire the ability to do all that the experience of years alone has taught the management of a State institution.

They tell us that County asylums should be built, and that they can be made equal in every way to State institutions.

Does not an appropriation for a County asylum begin and end in politics?

The statement that per-capita cost for the same degree of care is to be reduced by County care is false. It can never be reduced in the County as compared with State institutions, except by *a reduction of the standard of care.*

For this statement we have the authority of the figures and facts presented by Dr. Wise in his admirable paper, read before the County Superintendents of the Poor of the State of New York in 1886. His deductions are unanswerable; and the State Commissioner in Lunacy, Dr. Stephen Smith, confirms it in his criticism of the way the rules of the State Board of Charities are disregarded, in the following words:

"They have not been strictly conformed to in most of the asylums, but more lax methods have been adopted, greatly to the detriment of the service and general management."

To this testimony we can add that of visitors who have made thorough investigations, all of which goes to prove inferiority of care of the insane in these counties.

The present law does not work well. County asylums allowed to keep their chronic insane are keeping acute cases; while counties allowed to keep a certain number are keeping more than that number. Laxity will creep in, rules and regulations cannot be enforced, and as the number of County asylums grows the trouble must increase, till all intelligent State supervision will be lost.

A crying evil of the present law is the definition of the word "chronic."

The distinction is simply one of time. After two years the law really rules a case *incurable*, and the patient can be taken by the Superintendent of the Poor to his or her county and worked on the town farm. This is monstrous.

The bill now pending provides for the gradual return of all insane to State care, except in the counties of New

York, Kings, and Monroe. These latter counties are not exempted from the action of the bill for any reason except that it is not practicable at this time to legislate for them.

The State is to be districted, each district to have its asylum; increased accommodations to be provided as needed, and the details of transfer are most carefully provided for.

The State asylums, having their executive buildings and entire plant in readiness, can add, at insignificant cost per capita, the needed increase in accommodations.

The stand must be made on the medical merits of the bill, about which there can be no compromise, and it behooves every medical man to give to this humane and scientific measure all the support at his command.

DIGITALIS IN THE TREATMENT OF PNEUMONIA.

The use of digitalis in croupous pneumonia has often been recommended, usually in small doses, as a heart-tonic, but by some as a sort of specific. It has been claimed that the exhibition of very large doses of digitalis tends to abbreviate the course of the disease very remarkably, as well as to reduce the mortality. In most of the statistical tables prepared by the advocates of this method the defervescence is seen to occur from the sixth or seventh to the tenth day, which is the time at which the disease subsides ordinarily, so that not much would seem to be proved as to the virtue of the drug regarded as a specific.

In a recent graduation thesis, Dr. Ilie N. Antoniu, of Bucharest, reports one hundred and forty-two cases of pneumonia treated by Professor Petrescu with large doses of digitalis, and compares the results obtained with the average statistics of pneumonia. The digitalis was given in very large doses—from one to two drachms of the leaves in infusion in the twenty-four hours. In no cases, however, were any evil effects from these large doses observed, and the fatal secondary heart-depression, so feared by some authorities, did not occur. From a careful comparison of the cases reported, it does not appear that the disease was materially shortened, the defervescence occurring in most of the cases at the usual time. The mortality, however, was much below the average, the percentage being only a little over one, while in all the other tables, collected from various sources, the mortality is given as from three to twenty-four and a half per cent.

The author's conclusions, which are somewhat extravagant, are that it is possible to abort pneumonia by large doses of digitalis, especially if the treatment be begun early in the course of the disease. He maintains, also, that from sixty to one hundred and twenty grains of digitalis-leaves may be given in infusion in the twenty-four hours without any fears of heart-failure resulting from over-stimulation and subsequent fatigue.

VACCINATION AGAINST SEPTICÆMIA.

A COMMUNICATION has recently been presented to the Académie des Sciences, by M. Pasteur, which may possess a practical bearing of enormous importance. The communication is the work of MM. Roux and Cumberland, and it claims to show that immunity may be gained against septicæmia by the inoculation of certain soluble substances. The authors state that the septic microbe, in its growth, develops chemical products which act little by little upon it as an antiseptic. Finally it is destroyed by its self-engendered poison. That such a process occurs is in accordance with previously observed physiological facts. Roux and Cumberland have isolated these soluble products, and by carefully injecting them into guinea-pigs have made these animals incapable of being affected by the septic vibrio.

Of course it still remains to be proved that these experiments apply to man. Furthermore, it is well known that several different microbes may cause the phenomena known as septic fever, septicæmia, and pyæmia. But for all this, the principle of the method just described, if established, is an all-important one. It has been known that all the growth of microbes may be attended with the development of potent toxic agents. And it may be shown that this is the case with the bacillus tuberculosis. In the excretions of this parasite, then, we may look for the specific or prophylactic for phthisis.

A MEDICAL PARLIAMENT.

A NEW phase of medical politics has developed in Prussia with the organization by royal ordinance of a Parliament or Chamber of Physicians (*Aerztekammer*). The duties of the body thus newly started on its career will be, as the royal ordinance states, twofold: 1, To take into consideration questions affecting public health; and, 2, to act as the representative of medical interests.

It occupies a position somewhat between the British General Medical Council and the French Académie de Médecine, having less power than the former and more than the latter. The first election for representatives for the medical chamber took place on November 10th of last year. Twenty representatives were elected for Berlin, and twelve for the Province of Brandenburg, in all thirty-two, and an equal number of deputies. The first meeting of the new body took place on the 12th of the present month, under the presidency of Dr. Alhenbach.

It is needless to say that such bodies, which give authoritative utterances upon medical and sanitary topics, are of great value to the profession and the public. They elevate the dignity of the former, and they give direction and certainty to the opinions of the latter. It is most unfortunate that we as yet possess no such organization in this country. But our time will come.

THE MYCOLOGY OF THE FINGER-NAILS.

SOMETIME ago we called attention to the observations of Kümmel and of Forster on the methods of disinfecting the hands. Kümmel showed that this was a by no means easy matter, and recommended the use of hot water, soap, and brush, with a five per cent. solution of carbolic acid. Forster found that the use of sublimate solution (1 to 1,000 or 2,000) gave the best results, but to this Kümmel does not agree. Now Professor P. Fürbringer comes forward (*Annals of Surgery*, February, 1888) and shows that neither method necessarily touches the root of the trouble, for the tests of asepticity used—viz., touching or boring the finger into sterilized gelatine—did not take into account the micro-organisms which may lurk beneath the nail. When the filth of the subunguial space was cultivated in proper media, various micro-organisms developed, and this occurred even if the hands had been previously disinfected by the best known methods. Fürbringer extracted from the subungual space of such disinfected hands particles of matter almost macroscopically invisible, and deposited them upon sterilized gelatine. Assistants and chiefs of clinics were subjects of the experiments. Thirteen men were examined in this way, after they had most painfully and diligently disinfected their hands, fingers, etc.

The time employed in these detergent labors varied from two to ten minutes. The solutions used were carbolic or sublimate, combined with soap. In only one case were no cultures of colonies of micro-organisms obtained.

The author found that if any solution aided the disinfection of the hands better than another, it was sublimate. He also found that the following method gave the surest results, and the most perfect disinfection:

The nails having first been carefully trimmed and cleaned from visible filth, the hands are cleaned for a minute or a minute and a half with brush and soap, especially the subungual space. The hands are then washed in not less than eighty per cent. alcohol for a minute, and then before evaporation of the same they are brought into a 2 to 1,000 solution of sublimate or three per cent. carbolic acid solution, and washed for an additional minute. The advantages of the above are, first, the *certainty* of disinfection, the saving of time, the sparing of the hands, and finally the cheapness. By the above method either none or only one or two colonies (germs) were found in a culture. It is useful to know that in order to prevent decomposition of the bichloride in water, the author finds the following a stable solution, and equivalent after months to a solution of sublimate in distilled water, strength one pro mille: To two litres of clean well-water add 10 c.cm. of an alcoholic solution of sublimate (1 in 5) and one gramme of acid. aceticum.

THE CROWN PRINCE AND HIS PHYSICIANS.

THE medical profession will read with great satisfaction the bulletin of the Crown Prince's physicians denying the stories of quarrelling and conflicting opinions, and announcing that the physical condition of their patient is one of comparative comfort. It is greatly to be hoped that, in the conduct of a case which shows to the public so conspicuously the limits of our art, there will be nothing in the relations of the attending physicians which will detract from the dignity and honor of the profession.

We publish in full the bulletin of the physicians, dated at San Remo, March 6th.

"In view of the reports published in the press alleging differences of opinion among the physicians attending the Crown Prince of Germany, the undersigned declare that, as regards their ideas of the nature of the illness, no such divergencies exist. Just as little do they maintain that a dangerous turn in the malady is imminent. The sole responsibility for the conduct and treatment of the case remains, as prior to the recent operation, in the hands of Dr. Mackenzie. In the interest of the august patient, as well as of the people who esteem, love, and revere him, the doctors once more ask German and foreign papers to abstain from all discussion concerning his illness, or the methods or instruments used in his treatment.

"The local disturbances in the larynx have not appreciably altered. The wound has healed and the cannula lies comfortably. The patient's lungs are in a healthy condition. The cough and expectoration have diminished. The patient's strength is more satisfactory. His appetite is increasing. There is no digestive disorder, no pain on swallowing, and no headache. He sleeps, with interruptions, for hours together. As Dr. Bergmann's mission has terminated he will leave shortly.

MACKENZIE, KRAUSE, BERGMANN,
SCHRADER, HOVELL, BRAMANN."

THE DYSPNŒA OF BRONCHITIS.

CASES of bronchitis are so frequently met with that they usually call for very little medication, and generally yield to the ordinary expectorant treatment.

Far different is it with bronchitis of a subacute or chronic form, as well as acute bronchitis in the aged. No more distressing symptom than dyspnœa can be met with, and to combat this part of the disease is to relieve much anxiety, and often to cure the case.

Dr. Thomas R. Fraser, of Edinburgh, is a man most indefatigable in research. After having brought so recently to the notice of the profession the advantage of strophanthus in some forms of heart disease, he untiringly turns his attention to an investigation of the treatment of asthma and bronchitis (*American Journal of the Medical Sciences*). Finding that the nitrites and nitro-glycerine are of undoubted use in the asthmatic spasm of the bronchial tubes, he applies the same method of investigation to the dyspnœa of bronchitis, where also dry râles, having the same character as those that occur in asthma, are met with. On reviewing a large number of standard authorities, it is seen that the most important factor in the causation of these varied râles is considered to be a swelling of the bronchial mucous membrane. Dr. Fraser having noticed that these râles so often changed their seat, and not being satisfied with the explanation above given, undertook a series of experiments with the nitrites. His method was to carefully auscultate the chest, and after giving one grain of the nitrite of sodium, or some other of the nitrites, he auscultated the chest at short intervals, noting every change, subjective and objective. Out of a total of sixty-one observations, forty-eight were favorably influenced by the nitrites. Knowing the general effect of the nitrites on the circulation, he concludes that the cause of these sounds could not be intumescence by congestion of blood-vessels, or other results of inflammation, otherwise nitrites would increase, rather than lessen or suspend, the sounds. The nitrites, too, have no possible effect on the mucus collected in the bronchial tubes. He infers that the only explanation of the results of the observation that can reasonably be adopted seems to be that in bronchitis the rhonchi and sibili are frequently produced by contractions of the bronchial muscles; that dyspnœa is produced by the impeded movement of air, caused by the constrictions resulting from these contractions; and that both are removed by nitrites, because nitrites reduce the spasmodic contractions of the bronchial muscles. He finds the nitrite of sodium and nitro-glycerine, as stable preparations in solution, more suitable for administration by mouth or subcutaneously. Nitro-glycerine may be given in tablet or pill form, or in an alcoholic solution. He suggests giving the solution of nitrite of sodium with an alkali, as any acid, and in most cases the acid of the gastric juice, would tend to decompose the solution. The other forms of the nitrites, such as the nitrites of amyl and ethyl, are very unstable, and less well suited for administration. The ease with which such remedies can be administered, and the good reports from such a reliable authority, should make it incumbent on all physicians not to leave the nitrites untried in such anxious cases of dyspnœa, whether connected with bronchitis or asthma.

THE NEGRO FROM A MEDICAL STAND-POINT.

It has been asserted, time and again, by writers living at the North, who yet seemed to have reliable data upon which to base their belief, that the negroes in the Southern States were increasing at a much more rapid rate than the whites in the same section of the country. These writers based their assertions upon the census-returns and upon their own observations, and their conclusions seemed to be reliable. The weight of medical testimony is, however, against them, and the facts are, it appears, the reverse of what has been stated.

In a lecture delivered before the Georgia Historical Society, on June 6, 1887, and published in the New York *Medical Times* for October and November, 1887, Dr. E. B. Corson, of Savannah, reviewed the causes which were leading, apparently, to the extinction of the negro as a separate race in America. While they were held as slaves they were well cared for, as it was to the direct interest of the master to keep them in good health. They lived a regular life, and when sick had the most skilled medical attendance. Now, however, they flock to the cities, live in crowded quarters, are given to excesses of all kinds, and are seldom able to obtain as good medical care as they did formerly. At that time, too, the colored man could boast of his insusceptibility to malaria and yellow fever, and even pulmonary phthisis was comparatively unknown to him. Now, Dr. Corson states, this immunity is no more. The negro suffers almost equally with the white from malarial diseases, possibly as a consequence of the continually increasing admixture of white blood; and the mortality from pulmonary consumption is, as is well known, almost double that among the whites. Infant mortality among the negroes is very large, owing in great measure to the utter neglect of the most elementary hygienic and dietetic precautions on the part of those who have the care of young children.

In a paper read before the American Surgical Association, in May of last year, Professor Louis McLane Tiffany, of Baltimore, presented some statistics showing the comparative frequency of certain of the surgical diseases in the white and colored races. He had found that, while negroes bore injuries and operations better than the whites, surgical diseases involving the lymphatic system, especially if tubercular, were more fatal in negroes than in whites. Carcinoma he found to be very rare in the negro, the most common malignant growths being osteo-sarcomata. Rickets occurs with astonishing frequency in colored children, but congenital deformities are very rare. Specific affections of the genito-urinary organs are common enough among the negroes, and are apt to be more destructive because more commonly neglected.

Dr. Swan M. Burnett, of Washington, writes, in the *Archives of Otology* for December, 1887, concerning the relative frequency of ear disease in the white and colored races. He finds that ear disease is comparatively less frequent in the negro than in the Caucasian, and that the former rarely suffers from sclerosis, or dry catarrh, of the middle ear, which is the cause of so much deafness in the white race, although he is apparently more liable to suffer from acute catarrh. Nearly the same conclusions were reached by Dr. T. E. Murrell, of Little Rock, in a paper read before the Otological Section of the International Medical Congress, in September last.

Several other articles upon the condition of the colored race, as seen through medical eyes, have appeared during the past year; but it is unnecessary to review them, since their testimony all points to the same fact, viz., that the physical well-being of the negro has not been improved by emancipation, but rather the reverse. The pure negro has lost the protection which his master, through self-interest, even when not prompted by humanity, gave to him, and he suffers in tenfold degree from the few diseases which were his enemies in the olden time, while he also falls a victim to many to which he was a stranger then. The mulatto is even worse, for he has lost the immunity to certain diseases enjoyed by his fathers of pure African blood, while he has acquired none of the robustness belonging to the Anglo-Saxon. Unless a marked change for the better occurs soon, those who fear that the negro race will soon gain the ascendency over the whites, in the Southern States at least, may banish their apprehensions.

A SOLUTION OF THE SEWAGE DIFFICULTY.

Under this title a London engineer writes in the last number of *The Sanitarian*. His plan is to deodorize and precipitate sewage with ferric chloride. This agent he describes as "essentially a chlorinated compound of the higher oxides of iron, and possessing the remarkable property of parting with a portion of its nascent oxygen in the presence of putrid organic matter, or of matters approaching putrescence, and has little chemical effect upon organic compounds in a fresh state."

He claims that this agent is prepared from easily attainable materials, and from the waste products of certain manufactures. It can, therefore, be cheaply produced on the spot where its use may be required. "Having accomplished its work upon the sewage waters or other foul liquids, it then gathers up and reabsorbs oxygen, either from the air dissolved in the fluids or by splitting up water into its elements, for its own reconstruction, in readiness again for further duty, and so on in perpetuity."

In all refuse there are some healthy bacteria which act as scavengers, the so-called "nitrifying" germs. These the newly suggested agent does not destroy. It has a selective affinity upon the pathogenic and putrefying organisms. The advantages attending its use are summarized as follows:

1. Prevention of nuisances in the streets and thoroughfares by emission of foul gases and vapors generated within the sewers from putrefaction of sewage.

2. Prevention of nuisance in house-drains and their equipments.

3. Complete oxidation of putrescent organic matters,

combined with precipitation of organic matters in solution.

4. Precipitation in the settling tanks by simple subsidence and freedom from offensive smells during the operation.

5. Prevention of secondary decomposition in the sewage sludge, and fixation of nitrogenous compounds, thus securing whatever manurial value the sludge may possess, and avoidance of offensive odors in the process.

6. Arrestment of secondary decomposition in the effluent waters.

7. Economical treatment of sewage, and at less cost than by usual processes, combined with greater efficiency, due to the recuperative action of the fer-chlor.

8. Restraining effect upon disease and putrefactive micro-organisms, but without injury to the harmless and beneficial bacteria.

9. Avoidance of material alterations in the existing arrangement of sewage works, and equal adaptability of the process to towns discharging sewage into the sea or watercourses, or by irrigation of land.

News of the Week.

The Cartwright Lectures for 1888 of the Alumni Association of the College of Physicians and Surgeons will be given by Professor William H. Welch, of Johns Hopkins University, on Friday evenings, March 29th, April 5th, and 12th, at the college, at 8.30 p.m. The subject will be the General Pathology of Fever.

Montefiore Home.—There is a vacancy in the Attending Staff of the Montefiore Home for Chronic Invalids.

Typhoid Fever and Sewer-gas.—It is considered to-day by Professor Victor C. Vaughan a proven fact that typhoid fever may be conveyed by sewer-gas; so that we shall now have another bee in the sanitary plumber's bonnet. The story of the discovery, as told in the *Sanitary News*, is this: "An epidemic of typhoid fever has been prevailing at the Michigan State Prison at Jackson. A committee from the State Board of Health was invited to make an investigation of the causes of the epidemic. The water-supply and milk-supply were first ruled out as possible vehicles by negative evidence. It was then thought that the defective condition of the sewers, combined with the insufficient supply of fresh air, was the most probable cause of the epidemic. The cases nearly all were from a distinct portion of the prison, and investigation proved that the soil-pipe running from the hospital, and the house-drain, into which it entered, were defective, and were pouring sewer-air into that portion of the prison. Professor Vaughan took to his laboratory a sample of the air from within the soil-pipe, and has found within it the specific germ of typhoid fever." The only flaw in the argument lies in the fact that the etiological relation of the typhoid bacillus to typhoid fever is not yet incontrovertibly established.

The Bill for the Reorganization of Quarantine at this Port, abolishing fees and placing the Health Officer on a salary, has, at date of writing, passed its third reading. It seems likely that it will pass the Legislature.

The New Orleans Polyclinic is the name of an institution recently organized in New Orleans, and intended for the clinical instruction of students and physicians. Its first course opens in April. No doubt the school will prove a most helpful one, though it is spelled with a "y."

The Louisiana Medical Library Association is the name of an organization recently formed for the purpose of establishing a medical library, reading-room, etc.

A Hospital at Fitchburg, Mass.—A large sum of money has been left by the late Gardner S. Burbank for the establishment of a hospital at Fitchburg, Mass.

A Chinese Hospital.—We have received the first annual report of the Philander Smith Memorial, at Nankin, China. The total number of out-patients was 11,353, and of in-patients, 230. The terms of treatment are apparently very reasonable, for the authorities charge only five cents a day, with a deposit of $1 as security for good behavior. About one-half the in-patients are victims of the opium-habit. For these the treatment consists in a gradual withdrawal of opium.

Quinine is now quoted at from forty to forty-five cents an ounce.

The Kansas State Medical Society meets at Topeka on May 1st, 2d, and 3d.

The Gonococcus in Legal Medicine.—The number of physicians who are willing to testify on oath that the presence of the gonococcus is a positive proof of a gonorrhœal infection increases, and the small microbe is likely to assume mighty proportions before the court. The latest apostle of this view is Dr. P. Aubert in the *Lyon Médical*.

Epidemic Spinal Meningitis is said to prevail largely among horses in this city, and it is possible that it may be followed, as in 1871, by an epidemic affecting human beings.

Dr. Straus succeeds to the chair of Experimental Pathology in the Paris Faculty of Medicine, left vacant by the death of Professor Velpeau.

The Doctor's Carriage.—The late Dr. Biddle, of Philadelphia, is alleged to have held peculiar views on the question of the doctor and his carriage. He did his work (and he had a great deal of it to do) entirely on foot. The driving of one horse, he held, is evidence of physical weakness, and the driving of two horses is an indication of mental weakness.—*Medical Age.*

The Boston City Hospital is to have an out-patient department.

The Massachusetts State Medical Society and Homœopathic Diplomas.—A physician, Dr. Hipkiss, educated at a homœopathic medical college, has renounced dogmatic medicine and applied for admission to the State Medical Society. He is willing to submit to an examination, but is found to be ineligible because he has a diploma from a homœopathic school. An attempt is to be made to correct this manifest injustice in the requirements for membership.

Erythrophylœine.—Dr. John Tweedy writes to *The Lancet* that the alleged new anæsthetic, erythrophylœine, has no apparent anæsthetic power.

PROSTITUTION IN BRUSSELS.—The Royal Academy of Medicine of Brussels has unanimously passed a resolution to the effect that "the regulation of prostitution is necessary to check the propagation of venereal diseases." Other resolutions were passed, with few dissentient voices, in favor of prohibiting prostitutes from frequenting "streets, promenades, and public places," and providing for the periodical medical examination of recognized prostitutes.

THE PRESIDENT stated that the vacancy in the office o Corresponding Secretary, occasioned by the death of D Wesley M. Carpenter, had been filled by Dr. E. L. Keye

DR. ROBERT W. TAYLOR read a paper (see p. 261) on

XERODERMA PIGMENTOSUM AND ITS RELATION TO MALIGNANT NEW-GROWTHS OF THE SKIN.

THE PRESIDENT understood that in "

A SOCIAL MEDICAL CLUB, called the Galen Club, has been organized in London.

NOT DEAD.—The *Medical Press* recently announced that "our esteemed contemporary THE MEDICAL RECORD has ceased to exist." Not so, esteemed but ill-informed contemporary; THE MEDICAL RECORD was never more alive than at present, never was its circulation so colossal, its contents so interesting, its readers so absorbingly entertained, so practically instructed, or so gratifyingly communicative as regards the benefits bestowed by this same MEDICAL RECORD upon them in moral, intellectual, financial, and professional directions. THE MEDICAL RECORD is not dead; but the *London Medical Record*, its namesake, has changed its name.

THE FORTY-SEVENTH ANNUAL COMMENCEMENT OF THE MEDICAL DEPARTMENT of the University of the City of New York took place on Tuesday evening last, in the Metropolitan Opera House. A class of one hundred and fifty-seven was graduated. The address was delivered by Rev. William M. Taylor, the valedictory by Dr. W. B. Chapin. The Faculty prize of $200, or a hospital appointment, was awarded to Samuel Cummings. Prizes in the competitive examinations were awarded as follows: First, T. J. Dunn, who chose hospital appointment; second, W. G. Frey, $200; third, S. J. White, Jr., hospital appointment; fourth, W. M. McArtney, hospital appointment; fifth, L. R. Scudder, $100; sixth, E. L. Fisk, $50.

A TRAINING SCHOOL FOR NURSES EXISTS at the Eastern Illinois Hospital for the Insane, and is doing excellent work in fitting attendants for the care of this class of sufferers. At a recent Commencement thirty-two graduates received certificates.

DR. HENRY F. LYSTER, of this city, has been appointed successor to the late Dr. A. B. Palmer, in the chair of the Principles and Practice of Medicine in the Medical Department of Michigan University.

AN EMERGENCY HOSPITAL AND DISPENSARY is the name of a new institution just opened in Detroit. It will make a specialty of the care of accidents, and to that end it has in connection an ambulance, with trained attendants, subject to telephone summons night and day.

PROFESSOR R. A. F. PENROSE has resigned from the faculty of the Medical Department of the University of Pennsylvania. It is rumored that a *concours* is to be held. If this is so, it is probably the intention to select the Professor of Obstetrics from among the younger men.—*Boston Med. and Surg. Journal.*

HEALTH OFFICER OF BROOKLYN.—Dr. John Griffin has been appointed Health Officer of Brooklyn, in place of Dr. Andrew Otterson, whose term expired February 1st. Dr. Griffin is an Irishman and a graduate of Queen's University. He received his medical degree from Bellevue Hospital Medical College, in 1873.

SMALL-POX is prevalent in Brooklyn, the number of cases from January 1 to February 21, 1888, being one hundred and forty-five.

A HOSPITAL FOR CONTAGIOUS DISEASES is to be erected in Brooklyn, the sum of $20,000 having been appropriated for the purpose. We quite agree with the *Brooklyn Medical Journal* in protesting against its proposed erection outside the city limits.

LARYNGEAL PHTHISIS CURED.—At a recent meeting of the Berlin Medical Society, Professor Virchow exhibited a larynx, removed *post mortem*, that showed plainly a large tuberculous ulcer under one of the vocal cords, and, in addition—and this was the important point—a long, shining cicatrix, evidently following a tuberculous ulcer that had healed, thus proving that laryngeal phthisis may undergo spontaneous cure.

RELIGIOUS NEWSPAPERS THAT DO NOT ADVERTISE QUACKS.—The number of religious newspapers which do not insert quack advertisements is increasing. A list, which is not, we think, quite complete, is given in the *Medical and Surgical Reporter*. It includes *The Churchman*, *The Church at Home and Abroad*, *The Christian Register*, *The Church Record*, *The Moravian*.

PHOTOGRAPHING THE FUNDUS OF THE EYE.—M. Panel, of Paris, has invented a photographic machine by which the fundus of the eye may be photographed in a few seconds. This machine will enable a physician having a certain knowledge of photography to produce the image of a lesion situated in the eye.

A USEFUL ARTIFICIAL ARM.—M. Gripouilleau has invented an artificial arm, costing only about eight dollars, which will allow the wearer to dig, load, wheel a barrow, mow, etc. This arm, which is applied to the shoulder where the limb has been amputated, is made of wood, zinc, and sheet-iron.

THE ADVANTAGES OF THE SKIN OF BIRDS FOR SKIN-GRAFTING.—Dr. Redard has communicated to the Académie de Médecine of Paris some observations regarding animal grafts on wounds in human beings. In a case of severe burn of the scalp, of eight months' standing, in a child two years of age, he obtained a rapid cicatrization by means of grafts from a fowl. He first tried grafts of frogs' skin, but as these proved to be repulsive to patients and did not give very good results, he substituted others from the fowl, and the wound, which measured three inches by two and a half, had completely healed in two months. He had been equally successful in other and subsequent cases. He takes the skin from beneath the wing of a chicken, carefully securing the subjacent cellular tissue, but avoiding adipose tissue. The transplanted pieces varied from a sixth to a third of an inch in size, and they were maintained in position by means of a little cotton-wool and iodoform gauze. The skin of birds and fowls has the advantage of being supple, delicate, and vascular; it adapts itself readily to the surface of the wound, and adheres without undergoing absorption.

THE TABLET ERECTED TO THE MEMORY OF THE LATE AUSTIN FLINT, M.D., LL.D., by the Alumni Association of the Bellevue Hospital Medical College, will be formally unveiled at the Carnegie Laboratory, 328 East Twenty-sixth Street, at 8.30 P.M. on March 10, 1888. The presentation address will be made by Dr. Leroy M. Yale. The profession is invited to be present.

ANTIRABIC INOCULATIONS AT BARCELONA.—Dr. Ferran, who has charge of the pathological laboratory at Barcelona, has treated eighty-five cases of rabies by inoculations, without a death. Twenty-five of the patients had been bitten by animals positively known to be rabid. At first Dr. Ferran carried out the inoculations of his rabbits according to Pasteur's method, *i.e*, by trephining. Recently, however, he has adopted a new, and, as he believes, an improved plan, viz., the injection of a single drop of the emulsion of the medulla containing the virus into the anterior chamber of the rabbit's eye. This produces exactly the same effects in about the same time as the trephining method.

THE VENERABLE DR. COTTING, OF BOSTON, once at least in his lifetime, rose to such a considerable pitch of moral grandeur as to deserve our hearty commendation. "A notable family," the doctor says, "once sent for me. They had sickness in the house. Their family physician, they said, had become old, and so infirm that they felt obliged to give him up. They had long known of me and of my abilities and standing; had great regard for me, and they felt in this serious emergency that they could confidently trust in me—to tell them whom they had better employ as their physician. Keeping my self-possession as best I could, I told them, without apparent hesitation, whom I would send for were I ill myself. They sent for him, and he ever after attended them."

THE LAW AGAINST MUSIC AND BIER has been, says an exchange, applied to a Grand Army funeral with a band playing a dirge.

TEMPUS EDAX RERUM.—The proverbial belief that time cures all things, with the Cincinnati suffix, "Time will cure a ham," has received a curious substantiation in England. A London doctor, who had treated a lady-patient for a long time without giving her any relief, finally wrote her that he could do no more, and that *tempus edax rerum* was the only remedy. The lady at once started for a drug-store and applied for the remedy. She was given a bottle containing a mixture for which she paid $1.85. She continued using this, and at the end of a year and a half, accidentally meeting her physician, thanked him for his wonderful prescription, which had cured her. The druggist's trick was discovered, and she sued him for money spent on the bogus medicine.

AMERICAN DEGREES.—A correspondent of the *Medical Press* received a letter from a not very patriotic American regarding the value of American medical diplomas. He says: "I would not accept a present of an armful [of such diplomas] from American institutions, save and except a few, such as Harvard and Yale. Almost all others are downright trash, and discreditable to men educated in Great Britain and Ireland to hold. Those named would not, I think, confer degrees *in absentia*. Regretting my inability to aid you."

A SMALL-POX SPECIALIST IN ENGLAND.—Sheffield, England, is suffering from a plague of small-pox, it having no compulsory notification and vaccination law. A Mr. Herring came to the town and gave out that he could cure small-pox in two days. A memorial signed by two thousand persons, requesting the Mayor to convene a public meeting, was drawn up. The meeting was called, and Mr. Herring's claims enthusiastically pro-

A HOSPITAL AT FITCHBURG, MASS.—A large sum of oney has been left by the late Gardner S. Burbank for ıe establishment of a hospital at Fitchburg, Mass.

A CHINESE HOSPITAL.—We have received the first annual report of the Philander Smith Memorial, at Nan-
The total number of out-patients was 11,-

behalf of the town, and was escorted from the hall amid the cheers of the crowd.

SOLVENT TREATMENT OF URIC ACID CONCRETIONS.—Drs. Posner and Goldenburg have made some experimental observations in the laboratory attached to Dr. Lassar's clinic at Berlin upon the solubility of uric acid in some of the more notable mineral waters, and in alkaline solutions. Their experiments lead them to suggest that in cases of the uric-acid diathesis, especially in acute attacks of gout, the best and most powerful of such waters are those of Vals and Vichy. Less costly is the Fachingen; but others, such as the much-prescribed Wildungen, are not so efficacious as the prescription of bicarbonate of soda, in doses of from three to five grammes per diem, with plenty of water. Next in solvent potency comes Cantani's powder (of sodic bicarbonate, lithia, and potassic citrate), or lithium carbonate alone. In cases where only the diathesis has to be dealt with—*i.e.*, in the intervals of or apart from acute attacks—the Fachingen water is suitable, continued for a few days, or the weaker springs, and, as drugs, borocitrate of magnesia, borax, or Cantani's powder. The urine should not, however, be allowed to become alkaline.—*Lancet.*

THE DOCTOR IN FICTION.—In his remarks upon the value of novels during convalescence, Dr. Weir Mitchell takes occasion to discuss the doctor in fiction, and concludes that, with the exception of Lydgate in George Eliot's "Middlemarch," he is wholly unsatisfactory. This is somewhat severe upon the realistic author of "Dr. Breen's Practice," to say nothing of Miss Jewett, Jules Verne, Hannah More, and the delightful uncorseted female creations of Charles Reade. We are disposed to resent the acceptance of Dr. Lydgate, who was, after all, a weak man, as a satisfactory portrayal of the physician. We fear that Dr. Mitchell has something of a penchant for unpleasant types of doctors—perhaps through the chemism by which contraries are attracted. The New York doctor whom Henry James has described is "satisfactory," and his characteristics are correctly drawn, and Thackeray has given a description of a London doctor which certainly ought to be satisfactory.

A NEW CURE FOR HICCOUGH.—Dr. Dresch, of Foix, France, describes, in the *Bulletin Général de Thérapeutique*, a new and sure method of curing hiccough. The sufferer closes the external auditory apparatus with the tips of the fingers, making firm pressure. At the same time he is given water to drink in small swallows. The hiccough ceases instantly.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 2, 1888.

Abraham Jacobi, M.D., President, in the Chair.

The President stated that the vacancy in the office of Corresponding Secretary, occasioned by the death of Dr. Wesley M. Carpenter, had been filled by Dr. E. L. Keyes.

Dr. Robert W. Taylor read a paper (see p. 261) on

XERODERMA PIGMENTOSUM AND ITS RELATION TO MALIGNANT NEW-GROWTHS OF THE SKIN.

The President understood that in all cases of xeroderma pigmentosum there is absence, in considerable degree, of connective tissue and presence of a good many embryonic cells and elastic tissue. He asked Dr. Taylor whether he was correct in the belief that the connective tissue is wanting.

Dr. Taylor replied that the disease expends itself upon the papillæ rete. The connective tissue may be cut off by involvement of the overlying parts, but only by a mechanical process. This is more likely to occur over bony prominences.

The President was under the impression that the presence of a large amount of embryonic cells is one of the proofs of a relative lack of connective tissue. Then the best examples of this disease have occurred in infants, which goes to show that it is congenital. There is the further fact that malignant tumors develop in them at an early age. These facts, it seems, go to establish the view advanced by Cohnheim, that all pseudo-plasms, whether they occur in infancy, youth, or later in life, are the result of embryonic cells not undergoing the usual change into connective tissue or other tissues, but remaining behind, and afterward, for some cause or other, proliferating and forming a malignant tumor. The fact that the blood-vessels are not properly formed in the cases of xeroderma pigmentosum would seem to naturally follow where a large amount of embryonic tissue remains. Thus may be explained the nævous character of the whole surface. The fact that the reddened spots disappear and others reappear would seem to point to spontaneous thrombosis. The large vessels generally are not sufficiently formed, and a number of them become annihilated by thrombosis. Thus, it seemed to the President that the disease is originally due to arrest of normal changes in the embryonic tissue, which leads to the abnormal changes which afterward appear.

A SUGGESTION FOR TREATMENT

was based upon this view of the etiology of the disease, namely, to so nourish the blood-vessels and other tissues as, if possible, to change the character of the embryonic tissue remaining behind. Surgical treatment can do no good, further than to make the patient look a little better for a time after removal of tumors. But if new connective tissue can be made, perhaps that will do a good deal. He would therefore look for medicinal and dietetic treatment which may bring about that result. He thought that arsenic, and phosphorus particularly, might be beneficial in causing nutritive irritation. It is known that phosphorus, when given in minute doses, causes in a short time beneficial effects in rachitis, and in chronic and subacute bone affections. They should be administered intelligently and persistently, perhaps for a long period of time.

Dr. Taylor would avail himself at the first opportunity to carry out the President's suggestions regarding medicinal treatment, for methods already tried have been unsuccessful. Regarding surgical treatment of tumors already developed, he was convinced that it is rational, and has done good in the case operated upon by Drs. Gruening and Gerster. Of course, it would be desirable to so treat the case medicinally as to do away with the necessity for surgery.

SECTION IN OBSTETRICS AND GYNECOLOGY.

Stated Meeting, February 23, 1888.

J. E. Janvrin, M.D., Chairman.

Dr. H. J. Garrigues read a paper entitled

REPORT OF CASES OF LAPAROTOMY FOR RUPTURE OF THE UTERUS.

The first case which he reported was one which had not yet appeared in medical literature. He was called to see the patient in consultation, on January 21st of the present year. The patient had had six children, two of which had been delivered with forceps, and she said that all of her labors had been hard ones. Dr. Garrigues learned that the labor-pains had come on during the night between January 20th and 21st. The head presented. The bag of waters ruptured at about 5.30 P.M., January 21st. Noticing that the patient was growing nervous, the attending physician again made examination, when he found the head had receded, and rupture of the uterus had taken place. Dr. Garrigues was then called, and found the patient in poor rooms of a tenement-house. The child could be felt through the abdominal walls to the right of the contracted uterus. Vaginal examination showed the superior strait empty, and a large tear in the uterus, communicating with the abdominal cavity. The child was evidently large, while the conjugate diameter measured three and a half inches. Laparotomy was done, as the only possible means of saving the patient's life.

A median incision, about four inches in length, was made to the symphysis pubis. The first object to appear was the placenta. The membranes were easily removed. The child lay to the right, was dead and exsanguinated, and was estimated to weigh between nine and ten pounds. The abdominal cavity contained about a quart of fluid blood and some meconium. The rent in the uterus was eight inches long, ran chiefly in a transverse direction, and comprised the whole of the anterior and part of the posterior wall. Porro's operation was considered inexpedient. He therefore simply sutured the uterus with silk. It was quite difficult to reach the under tear, making it necessary to employ a double set of sutures, the one including the entire walls except the endometrium, and the other closing the peritoneum. As many as thirty-seven sutures were required to prevent folding-in of the peritoneum. The abdominal cavity was washed out with plain warm water until it came away clear. The uterine cavity was washed out with bichloride solution. The patient lived four days, when she succumbed to peritonitis.

It was to be remarked in this case that antiseptic conditions had not been observed before Dr. Garrigues saw the patient, nor was it possible for them to be fully carried out afterward, because of the patient's surroundings. She received the most unsatisfactory nursing, subsequent to the operation, from ignorant friends and relatives.

Dr. Garrigues then gave a summary of some published statistics of rupture of the uterus, and said it appeared from them that the accident occurred once in about five thousand deliveries. During his connection with the New York Maternity Hospital the past six years, it had occurred once in about three thousand deliveries. It took place oftener than the published cases would indicate, for many fatal cases had doubtless not been published.

Regarding the etiology, it was the rule that the accident occurred in those who had borne many children. His own case was no exception. He looked upon the disparity between the size of the child and the pelvic diameters as another important factor.

The prognosis is bad. The child almost invariably dies, and but few mothers escape. The statistics of one hundred recoveries in over five hundred cases were misleading, as all recoveries are reported, while doubtless fatal cases are often not reported. The chief causes of death are hemorrhage and peritonitis. Considering the large size of the child and the proportionately small size of the pelvic diameters in this case, he would, had he been called to it before rupture occurred, have suggested Cæsarean section in preference to other measures.

Dr. Malcolm McLane had had two cases of rupture of the uterus, both of which he had reported before the Section about two years ago. One of the patients recovered; the other was hopeless when he performed laparotomy, and died soon afterward. He believed rupture of the uterus occurs much more frequently than is generally supposed. He had seen during the past nineteen years two other cases, and had heard of others in his neighborhood. In his successful case only a part of the child had escaped from the uterus, and he extracted, after version, by way of the vagina. The rent was in the lower portion of the uterus, and the membranes had protected the peritoneal cavity from blood. For that reason he did not perform laparotomy, preferring to give the woman the chance of recovery without it. A hæmatoma formed, but otherwise the recovery was without interruption. He had lately delivered the woman of another child at term.

Dr. R. A. Murray had seen four cases of rupture of the uterus, all of which terminated fatally. Three were supposed to be incomplete ruptures, but two of them proved to be complete, and the third was made complete by gangrene. He was convinced that what were supposed to be incomplete ruptures occurred quite frequently, and that many of them were really complete ruptures. As an autopsy was not made, and death was ascribed to puerperal peritonitis, the cases failed to go on record as those of rupture of the uterus. Dr. Murray raised the question whether, when the child was delivered by the natural passages, and the mother had recovered from the shock of the injury, it would not be proper to perform laparotomy, if for no other reason than to thoroughly cleanse the peritoneum. In two hospital cases they had attempted to secure antisepsis by drainage, but the attempt was a failure, notwithstanding there was no fetor to the lochia. In three cases the house physicians had failed, notwithstanding their presence at the bedside throughout the labor, to recognize rupture until symptoms of collapse developed.

Dr. J. P. Garrish had seen one case of rupture of the uterus, in which Cæsarean section was performed as soon as the accident had been recognized. He believed in prevention, and therefore applied a bandage from the armpits to the hips during labor, and placed two or three folded towels beneath it over the abdomen.

Dr. R. A. Murray then read a paper on

THE INDICATIONS FOR THE USE OF THE INTRA-UTERINE DOUCHE IN THE PUERPERAL STATE.

The subject was considered under three heads: First, what are the indications for the intra-uterine douche; second, the method of its employment; third, the contra-indications and dangers connected with its use.

The author opened his paper with the recital of a case illustrative of the want of appreciation among physicians of the value of the intra-uterine douche in the puerperal state. The patient lived in a malarial district, which led her physician to regard the fever and other symptoms of blood-poisoning from retained membranes as due to malaria. In spite of her steady progress toward recovery, after Dr. Murray had made intra-uterine injections of an antiseptic fluid, her physician continued to deprecate the use of the douche as meddlesome midwifery.

As a prophylactic measure the intra-uterine douche is sometimes indicated in what are regarded as quite normal labors. In cases in which there is a prolonged second stage, during which the acrid discharges are constantly bathing the vaginal canal, the uterus subsequently relaxing easily, the patulous condition of the genital tract allows of the easy introduction of germs. The douche in such cases not only cleanses the canal, but the effect of the hot water is to promote permanent contraction of the uterus and to close its sinuses. Long labors, even where instrumental aid has not been given, are frequently followed by fever. The shorter the labor, other things being equal, the greater the safety in the puerperal period. When the hands or instruments are introduced into the uterine cavity for the purpose of removing the placenta, etc., there is likely to be more or less bruising and infection of the genital tract, and the douche will have the effect of washing away clots and disinfecting the injured tissues with which it may come in contact. There are also cases in private practice as well as in hospitals of patients showing marked prostration and fever during confinement, being surrounded by an atmosphere favorable to the development of sepsis. In many such conditions one intra-uterine douche, given after labor, would, he thought, render the entire genital tract antiseptic, and avoid fever and the necessity for subsequent interference. When, subsequent to delivery, the lochia become scanty and there is a suspicion that all is not well, one should not content himself with the fact that the lochia are not fetid, but should make a careful examination of the genital tract, and if the cervix be in a patulous state, and the finger has a fetid odor, the indications are to cleanse the uterus at once. The guide to be followed is the septic or the aseptic condition of the uterine cavity. If after the first washing chill and fever occur, and the lochia become fetid with no other apparent cause, the uterus should again be douched. The only instruments required with which to make the douche are a long rubber tube to attach to the intra-uterine tube, the latter made preferably of glass; a thermometer, a sheet of thin rubber cloth, a proper supply of hot water of a temperature of 110° F., and instruments with which, if necessary, to curette the uterine cavity.

The objections which had been urged against the douche were, the disturbance of the patient, the introduction of the finger or tube into the uterine cavity, and the possibility thereby of bruising the parts and causing infection; after the injections, the danger of collapse, the forcing of air into the veins, and the passage of the tube into the peritoneal cavity. In answer to these objections, the author drew attention to the fact that the patient is not lifted at all, but is merely moved around to the edge of the bed, nor is the head raised to endanger syncope; no air can be introduced with the tube, as the water flows during introduction and withdrawal; if introduced properly the endometrium will not be injured; shock, collapse, and peritonitis may be avoided by the assistant firmly grasping the uterus, not pressing downward, but preventing distention of the uterus, and by keeping the cervix patent with the finger. Carbolic-acid or other poisoning by the injected fluid cannot occur if firm contraction of the uterus is maintained, during the injection and subsequently, by ergot. Iodoform had been employed occasionally for protection of the mucous membrane, but Dr. Murray thought it concealed the odor of the lochia, and in that respect is objectionable. The injection should always be made by the physician, and never by the nurse. Only a limited number of labor cases require the intra-uterine douche, but in the classes described it is necessary.

Dr. Andrew F. Currier thought the value of the intra-uterine douche in sepsis after labor had been fully proved, but he did not think it should be used in every case of labor, merely as a prophylactic measure. He had found the Chamberlain glass tube excellent, and the only other quality which he could desire it should possess is that of flexibility. He referred to a case in which a flexible tube was allowed to remain in the uterine cavity after the first washing, and it decidedly favored drainage and facilitated subsequent injections.

Dr. H. J. Boldt did not change the patient's position in bed, but used an ordinary bed-pan as a receptacle for the outflowing douche. To equalize the inflow and outflow he constricts the tube through which the fluid escapes, near its attachment to the bed-pan. He uses plain hot water. By leaving a gum-elastic catheter in the uterus, and employing a fountain syringe, the nurse can make the injection without the aid of the physician. When it is necessary to make a single injection for prophylaxis, as in cases in which the attending physician has neglected antiseptic measures, while introducing the hand or instruments into the uterus, he employs an antiseptic solution.

Dr. Malcolm McLane drew attention to the fact that the holes in the Chamberlain tube sometimes extend down as far as four or five inches from the end. They should be limited to within two inches of the end.

Dr. A. P. Dudley uses ergot in every confinement case, and thinks it prevents the development of sepsis. He has never seen any harm from it. He could not see the necessity for using an antiseptic in the injected fluid, and emphasized its dangers.

Dr. H. J. Garrigues preferred corrosive sublimate as the antiseptic (1 to 4,000), limiting the quantity to within three pints. He employed iodoform pencils after the injections, which rendered it unnecessary to use the douche oftener than once in twenty-four hours. The uterus should be squeezed out after the injection, to empty it of the poisonous fluid. Chloride of zinc should be applied to diphtheritic spots.

Dr. P. F. Mundé said that when he is called to a puerperal case in which there is a rise of temperature and offensive discharge, he proceeds at once to introduce the finger into the uterus, and finding membranes or clots, removes them, and then makes an injection of hot water. Corrosive sublimate should not be used in any of these cases; poisoning has resulted so frequently that he considers its use bad practice. Its germicide properties in washing out the uterus are of no value. When there is nothing in the uterine cavity to be washed out, irrigation is useless, if not worse than useless. He does not always expect the temperature to be reduced by the douche; for if that were the case, death would never result during the puerperal state, as it would only be necessary to use the intra-uterine douche. If the temperature does not go down, he looks for other remedies. He had seen most decided chill and subsequent rise of temperature follow hot irrigation. Severe shock has also attended its use. He wished to call attention to the fact that intra-uterine irrigation may be dangerous, and it should not be employed when not called for. He had seen it used in active peritonitis or cellulitis. He would not use the iodoform pencil in the uterine cavity. In fact, he doubted whether it has any germicidal properties.

Dr. Murray, in closing the discussion, said he believed with Dr. Mundé, that danger attends the use of the intra-uterine douche, and therefore it should be used with care, and only in cases in which it is indicated. A patulous os shows subinvolution, and when the finger has a foul odor after introduction into the os, it is an indication of some form of decomposition there present, and the douche is indicated. An antiseptic is necessary to check commencing decomposition on the surface tissue, which washing with simple water will not disinfect. Bichloride of mercury is the best agent for this purpose. He employs ergot, as a rule, but closure of the mouths of the sinuses and veins will not alone prevent absorption of septic matter when this is present. When the system has once become poisoned with septic material, washing out the uterus alone will not cure the patient; but it should be employed sufficiently to prevent further infection. There may be other causes of puerperal fever than absorption of septic matter from the uterus.

The Uterine Lochia in the normal puerperal state contains no micro-organisms, and may be introduced into the bodies of animals without harm. The vaginal lochia, however, always contains a number of germs of various kinds, which will, when injected into animals, cause abscesses. In fever there are septic germs in the uterine lochia. Such are the results of a bacteriological research made by Dr. Döderlein, of Leipzig.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting held Tuesday, February 8, 1888.

C. L. Dana, M.D., President, in the Chair.

Dr. J. B. Emmerson presented a pile of

RECTANGULAR PRISMS IN A SINGLE FRAME.

The pile consisted of Nos. 2, 4, 6, 8, 10, 12, 14, and 16, which were fixed, and two additional prisms, Nos. 1 and 16, which were movable. By subtracting, Nos. 3, 5, 7, etc., were obtained; and by adding, Nos. 18, 20, 22, etc. The apparatus was used in the same way as ordinary prisms, the advantage claimed being increased facility in rapidly changing one prism for another. The muscles could be tested in one-fourth the usual time. The cost was $16; the ordinary set costs $12.

Dr. Ira Van Gieson presented specimens of

THE BRAIN-CORTEX STAINED BY GOLGI'S METHOD.

Blocks, one to two cubic centimetres in dimensions, were subjected to the action of a two to five per cent. solution of bichromate of potash. The time required for hardening varied with the temperature. A constant temperature of 20° to 25° C. was preferred. In the summer, hardening was completed in fifteen or twenty to forty or fifty days. In winter, five to fifteen weeks were required. In changing the bichromate solution its concentration was increased up to five per cent.

After hardening, the specimen was placed in a solution of nitrate of silver, three-fourths of one per cent. as an average. Where the hardening was incomplete, one per cent. solution might be required. The same result could be obtained by immersion in a corrosive sublimate solution of one per cent. strength, but months were required by this method. The speaker thought it also less certain than the one described. Both methods had been modified by Pal, of Vienna. The modification required the immersion of the silver or sublimate sections in a one per cent. solution of sodium sulphide, which produced a more complete precipitation in the finer processes.

The object of the method was the staining of ganglion-cells and processes, the matrix being left clear.

Literature in connection with the subject was cited, as follows:

1. C. Golgi: "Recherches sur l'Histologie des Centres nerveux," Arch. Italiennes de Biologie, vols. iii., iv., 1883.
2. C. Golgi: "Sulla fina Anatomia degli Organi centrali del Systema nervoso," Milano, 1886.
3. Professor Forel: "Einige hirnanatomische Betrachtungen und Ergebnisse," Arch. f. Psychiatrie, Bd. xviii., No. 1.
4. Bleuler: *Correspondenzblatt f. Schweitzer Aertzte*, March 15, 1886.
5. J. Pal: "Ein Beitrag zur Nervenfarbentechnik," *Med. Jahrbuch der K. K. Gesellschaft*, 1886, No. 8.
6. C. Mondino: "Recherche macro e microscopiche dei Cerebri nervosi," Torino, 1886.
7. Marchi: "Sulla Struttura dei Corpi striati e Thalami ottici" (Memoir dal Instituto Lombardo di Scienze e Lettere, 1887).
8. Tara Tufi: "Sull' Anatomia della Retina," *Internat. Monatsschrift f. Anat. u. Phys.*, Bd. iv., Heft 10.
9. L. Petrone: "Sur la Structure des Nerfs cerebro-rhachidiens," *Internat. Monatsschrift f. Anat. u. Phys.*, Bd. v., No. 1.

Dr. Dana also presented specimens stained by Golgi's method. He had not so far been so successful as Dr. Van Gieson, but in a few specimens he had got staining which showed one interesting peculiarity of the method, viz.: that it at times stained cells of one class; at others, those of another. In his sections the connective-tissue cells only were stained, but these were shown in a striking manner. Obersteiner had stated that by the sublimate method only about one-tenth of the cells were stained. The speaker thought that Golgi's method was a truly epoch-making discovery, comparable to that of Weigert for the nerve-fibre, but, naturally, great care would be required in drawing conclusions from what was seen. He presented Marchi's monograph on the structure of the optic thalamus and corpus striatum, in which it was shown that the cells of the former ganglion were chiefly of the motor type, and those of the latter chiefly of the sensory.

Dr. Sachs asked whether any facts had been demonstrated by Golgi's method which had not been shown by others.

Dr. Van Gieson replied that we have no other method which will stain the ganglion-cell. Golgi's method had shown the axis-cylinder as a branch of the nerve-cell. It had shown, also, that the protoplasmic processes do not inosculate.

Dr. Birdsall objected to this inference. We had no means of knowing that, even by this method, the whole of the process was stained. By Golgi's method we could trace the process farther than by other methods, but we could not say that finer subdivisions, which the precipitate failed to indicate, did not exist.

Dr. A. D. Rockwell read a paper on

NEURASTHENIA AND LITHÆMIA.

A diagnosis of neurasthenia was often made where the stomach and liver were chiefly at fault. Neurasthenia, on the other hand, was often mistaken for lithæmia. Mental depression was common to both; but irritability was peculiar to lithæmia, and the tongue was coated and the pulse slow rather than fast. Neurasthenia presented many symptoms; those of lithæmia were few, and cases were much alike.

In treatment, lithæmia responded to mineral waters and restricted diet; while in neurasthenia relief from work and anxiety, and increased feeding, were required.

Dr. Birdsall remarked that the term neurasthenia was used to cover a variety of nervous disorders not due to organic disease. The term lithæmia also was commonly used in a vague and incorrect manner. He thought it impossible to make a division between the clinical features of the two conditions. There were many intermediate cases which would disprove any classification. All were probably but parts of a vast group of nerve-disturbances based upon faulty conditions of nutrition. Absence of anxiety and rest had a direct effect upon digestion. The results of treatment presented no ground for the conclusions named. Heredity was a marked factor.

Dr. Sachs stated that for a long time he had been sceptical of a true set of lithæmic symptoms, but that he had found them in private practice, and had followed up a number of cases. He agreed with the previous speaker in regarding neurasthenia but a nervous disturbance, of which lithæmia might be an etiological factor. Lithæmia had been, in his experience, almost limited to women of the wealthy class, suffering from an inactive life. Nervous symptoms were proportioned to the amount of uric acid in the urine. With increased exercise or prolonged massage, the uric acid disappeared and the patient improved. Referring to the question of heredity, he considered cases with hereditary lithæmic tendencies as gouty, and when neurasthenic, he classed them as cases of neurasthenia upon a gouty basis.

In treatment, he agreed with the reader of the paper. For lithæmia he used cholagogue cathartics, physical exercise, and massage.

Dr. Birdsall explained that he had referred to the inheritance of neurasthenia, not of the lithæmic symptoms.

Dr. Leszynsky had met with cases which merited the name lithæmic neurasthenia. He recalled a case in which nervous symptoms had alternated with gouty manifestations. He had watched this case for two months, during which no diagnosis but that of neurasthenia could be made. At the end of that time a true gouty attack had developed. While the gout lasted the nervous symptoms were absent, but these returned when the gout disappeared. Concentration was common in neurasthenia and other states.

The speaker added that the late Dr. McBride had been accustomed to say that all neurasthenia was caused either by lithæmia or muscular anomalies.

Dr. Emmerson had seen neurasthenia cured by the correction of errors of refraction and muscular anomalies.

Dr. Dana favored the classification of neurasthenic symptoms into further clinical groups, the subdivisions to be based upon the etiology, symptomatology, and the chief seat of the disorder.

Etiologically, there were the hereditary and the acquired forms. Among the acquired were to be placed the lithæmic, etc. He did not think that lithæmia could be sharply separated from neurasthenia.

Symptomatologically, there were the irritative and the depressive forms.

Anatomically, there were the cerebral, gastric, and sexual forms. By establishing symptom groups, we might eventually make some progress in dealing scientifically with what was at present a vague condition. In the classification here, as in insanity, the various factors above indicated would for the present have to be used.

Dr. Rockwell explained that he had not represented neurasthenia and lithæmia as separate types of disease. He had not said that there was a distinct dividing line between them. He agreed at to the lithæmic origin of neurasthenia in some cases. There was, however, a distinct difference in the behavior of certain cases toward food. In the purely nervous case an abundance of albuminous food was indicated, while in lithæmia the quantity of such food was to be curtailed. Notwithstanding the existence of intermediate cases, there were others which were distinct, requiring distinctive treatment.

Dr. Dana asked whether Dr. Rockwell excluded albuminous food in lithæmia.

Dr. Rockwell replied that he did. He had, indeed, cured himself of excessive irritability, accompanied by lithæmia, by dispensing with meat and living mainly on a farinaceous diet.

Dr. Dana referred to the fact that Dr. Draper had, in the Practitioners' Society, about two years ago, recommended a purely nitrogenous diet in these cases, and this was, he believed, the prevalent habit in treating lithæmia, as ordinarily understood. He had followed it in his own practice, but latterly with a conviction that it did not always answer.

Dr. Birdsall stated that he, too, had followed Dr. Draper's rule. In defective digestion, sugars and starches were many times at the bottom of the trouble. Fats, too, were often the offending agent. It was not even known that uric acid was the poison in these cases.

Dr. Sachs, in his treatment, preferred non-nitrogenous to albuminous food.

Pathogeny of Hydatid Urticaria.—Urticaria sometimes follows the puncture of hydatid cysts and the spontaneous rupture of them into the peritoneum. Some slight irritant in the hydatid fluid, becoming absorbed into the circulation, is held to be the mechanism of production of the urticaria. M. Debove has attempted to prove the truth of this theory by injecting hydatid fluid into the subcutaneous tissues of individuals never having had nettle-rash. In one nothing happened; the second developed a local urticaria; and the third showed characteristic swellings about the site of puncture, and four large plaques on the posterior part of the trunk, twenty minutes after the injection; six hours later there appeared a confluent and typical eruption on the front of the arms and forearms. This kind of experimentation, from a logical point of view, is not perfect. A much larger number of injections should have been made to be of value, because different individuals vary greatly in their mode of response to mere injections of apparently inert fluids. Nevertheless, the observations are interesting, though made by experimentation which would hardly find favor in England.—*The Lancet*, January 7, 1888.

OUR PARIS LETTER.

(From our Special Correspondent.)

ANALGESIC ACTION OF ANTIPYRINE—CAUSE OF DEATH FROM INHALATION OF COAL-GAS.

PARIS, February 24, 1888.

AMONG the numerous therapeutic applications of antipyrine, Dr. Legroux, physician to the Hôpital Trousseau (hospital for children), has lately brought to notice its value in the treatment of chorea. The analgesic action of antipyrine, explained by its influence on the elementary nutrition of the nervous system, extends also to the motor sphere. In an experiment performed at a meeting of the Société de Biologie, Professor Bouchard demonstrated that if one of the sciatic nerves of an animal under the influence of antipyrine be cut, the ensemble of the muscular system enters into resolution, with the exception of those muscles which receive nervous filaments from the divided sciatic nerve. Guided by the observations of Dr. Dujardin-Beaumetz concerning the sedative action exercised on the reflexes by the nervous antithermic agents, Dr. Legroux experimented with antipyrine in the treatment of chorea. He cited six cases of cure of the malady, more or less ancient, obtained by the administration of three grammes per day during a period extending from six to seventeen days, and without the manifestation of any sign of intolerance for the drug. This is considered a great therapeutic victory, as the affection in question, the average duration of which is from seventy to eighty days, may now be suppressed in the course of a few days.

Antipyrine has also been employed for arresting hemorrhage, whether external or internal, but at a recent meeting of the Société de Thérapeutique it was shown that the internal administration of the drug for this purpose was of no value, but externally it was a powerful styptic and antiseptic.

Like all drugs that have a certain vogue, antipyrine has been much abused by its too indiscriminate use in almost every case that is now brought to the notice of the physician. At a recent meeting of the Academy of Medicine, Professor Ball read a note for Dr. Oscar Jennings, in which the author brings to notice some of the toxic effects of this most useful remedy. He related, among others, the case of an old lady affected with chronic rheumatism. On January 23d, Dr. Jennings prescribed two and a half grammes of antipyrine, to be taken daily. On January 31st this patient was surprised to find her arms covered with an erythematous eruption. On the following night the feet were icy cold. On the next day the face became red and swollen, the eyelids almost completely closed by the swelling. The rash became generalized, the patient lost all appetite, and she felt a peculiar sensation as if her whole body were filled with ice. The next day the eyes presented a catarrhal conjunctivitis, which would give one the idea of an iodic intoxication. The body temperature was lowered. These symptoms were combated by the administration of a few doses of the tincture of belladonna, and, of course, the antipyrine was suspended. A rather warm discussion followed, in which Professor Germain Sée took the most active part. He expressed his surprise that the patients treated by Dr. Jennings with antipyrine should have been affected as described by him, and he can only attribute the result of the administration of antipyrine, in the cases referred to, to idiosyncrasy, as he had frequently administered the drug in much larger doses without any evil effects resulting therefrom. He vehemently protested against the employment of belladonna or atropine, as recommended by Dr. Jennings, to combat the toxic effects of antipyrine, as being irrational and dangerous.

M. Gréhant has analyzed the gas which proceeds from the combustion of coal-gas, or that employed for lighting, and he submitted, at the last meeting of the Société de Biologie, the following as the result of his researches. He ascertained that the air in which a gas-lamp burns contains as much as 5 c.c. per cent. of carbonic acid, and that the oxygen diminished to a little more than half of its normal proportion. He therefore concludes that, in the rooms where there are one or more gas-lamps burning, it would be advisable to place above them a small funnel communicating by a tube with the exterior, in such a manner as to prevent the vitiation of the air.

According to Dr. P. Bruneau, in an article published in the Annales d'Hygiène Publique, the author states that when coal-gas suddenly penetrates into the lungs, the victims are at once struck down. More frequently the grave incidents which precede the prodromata are more or less intense and durable, such as a peculiar languor, inappetence, cephalalgia, followed by giddiness, nausea, and even vomiting. To these symptoms, which disappear when the patient removes from the place, succeeds a profound trouble of all the faculties, and in an instant there is total loss of consciousness and prostration of strength. The respiration is affected and death soon follows, with the phenomena of asphyxia. These accidents may be observed as well among those who work in gas-manufactories as in private individuals who are daily subjected to the emanations of burning coal-gas, which emanations little or no attention is paid to, as one gets accustomed to them. In case of intoxication by the gas, the first indication consists in removing as soon as possible the patients from the place where they became affected, and in employing proper means to favor the oxygenation of the blood, and in stimulating the economy. Artificial respiration by different means should be employed, followed by inhalations of oxygen. The body should be well wrapped up and revulsives applied. Bleeding, at this moment, would have the good effect of preventing the accumulation of blood in the organs. It is even logic to believe that the organism would greatly benefit from the transfusion of blood into the veins, as it would have the effect of infusing new blood into the patient. If it be a case of medical jurisprudence, and it be necessary to ascertain the cause of death supposed to be due to burning gas, the expert may find himself perplexed in the case where the gas filtering through the soil should be freed of its odor. In such a case experiments should be performed on animals, such as dogs, for instance, in the place contaminated by the gas, and the phenomena presented by them should be properly studied and the blood submitted to spectral analysis.

OUR CANADA LETTER.

(From our Own Correspondent.)

A NEW DEPARTURE IN MEDICAL EDUCATION—MEDICAL RECIPROCITY—CANADIAN QUACKERY—NEW HOSPITALS—A PROVINCIAL MEDICAL LIBRARY—ACTION FOR MALPRACTICE.

March, 1888.

THE cause of higher medical education in Canada has, it is generally admitted, been strengthened by the establishment of a medical faculty in connection with the University of Toronto, an institution supported by, and under the control of, the Government of the Province of Ontario. The chief promoters of the scheme are now congratulating themselves on the successful inauguration of this strong arm of our national university. The various schools of medicine in the Dominion have been doing good work, but while this fact was admitted there has, for some years, existed a feeling in favor of having, in connection with the Provincial University, a faculty of medicine whose aims and efforts would command the sympathy and support of the profession and the general public. There has, too, during recent years, been a marked desire for a confederation of the various degree-conferring institutions of Ontario with the Provincial University, and a strong feeling that the consummation of such a union would raise the standard of education required for the different professions. Canada prides herself on the superiority of her educational institutions, and the increased interest shown in the welfare of her colleges and universities is certainly a hopeful sign of the times.

In these days, when Reciprocity has become the watchword of some of the politicians, the opinion has been expressed that steps should be taken to render more accessible admission to American physicians desiring to enter the ranks of the profession in the Canadian Provinces. At present, while every year Canadian medicos settle in different parts of the United States, the strict rules of our provincial medical councils are such as to exclude from practice all who have not passed through a regular course of four years of professional study (one session of which must be spent at one of our Canadian colleges), and passed the regular examination of the Medical Council. This final examination must be passed by everyone before a license to practise is issued, so that the young Canadian with his college-won M.D. must, if he desires to locate in his native province, submit to a second examination. The penalty for practising without the diploma of the Medical Council is a severe one, and the law is so well enforced that few irregulars are left. Canada has no homœopathic or eclectic schools of medicine.

The Dominion, however, cannot be regarded as a medical paradise, free from the presence of the genus quack. Occasionally some weak member of the fraternity, who has attained regular qualifications, falls from grace and, forsaking orthodox methods, enters the field, and with fulsome, bold advertisements proclaims his wondrous skill (?) through the public prints. Toronto, Montreal, and some other large cities are generally chosen as their abiding-places, and the smaller towns are spared the infliction of their presence, except when occasional visits are made by some of these worthies.

Canadian liberality has lately manifested itself in generous donations to several hospitals. The gift of $500,000 to Montreal by Sir George Stephen and Sir Donald Smith, for the erection of a new hospital in that city, has encouraged some of the citizens of Toronto to start a fund for the erection of another hospital in the Queen City, and the Hon. John Macdonald (not Sir John A.) has lately donated $40,000 for that purpose. The hospital accommodations of these two leading Canadian cities will be greatly increased by these munificent gifts. A new hospital for sick children is at present in course of erection in Toronto, and when completed will, it is claimed, be the most convenient and perfect children's hospital on this continent. The Medical Library Association of Ontario has had a successful commencement, and already a large number of valuable works have been contributed. The library is established in Toronto, but members of the profession in any part of the province can readily enjoy the privilege of membership.

An action for malpractice has recently been tried in Hamilton, the defendant being Dr. Leslie, an old and highly esteemed practitioner of that city. The plaintiff was the widow of a man who died during the administration of chloroform by Dr. Leslie. There was no evidence to show any lack of care or skill in the administrator, but the jury unfortunately failed to agree, notwithstanding the fact that nearly a score of leading medical men testified in favor of the defendant. The case may be tried again, and even if the doctor wins in the end, it is extremely questionable whether he can recover his costs. As Canadian law at present stands, any practitioner, no matter how careful, may be subjected to an expensive trial by an irresponsible patient, who is not asked to give any security for costs. This leaves many a medical man who may win his case with the reflection that, although he has vindicated himself, he has little or no prospect of collecting the expenses of the trial from the person who has subjected him to so much annoyance. It is generally the worthless that bring such suits. The feeling prevails that in such cases trial by jury, that fossilized bulwark of English liberty, is little short of a huge farce. It does seem absurd that the treatment of a case by a medical man should be pronounced upon by a body of men utterly ignorant of the intricacies of medical and surgical cases, and susceptible to sentimental influences which too frequently influence decisions in such cases.

INSUFFICIENCIES OF THE OCULAR MUSCLES.

To the Editor of The Medical Record.

Sir: In your issue of February 4th, Dr. Stevens, not satisfied with all the authorities already cited, makes a request for some more, in regard to the insufficiencies of the ocular muscles, and particularly in regard to insufficiency of the externi and the tenotomy of the internal recti where there is no strabismus.

Turning to Donders[1] we find quite an elaborate discussion on this subject, in which the following occurs: "We may also assume that, even when asthenopia existed without strabismus, the rest, which the patient had to observe for some time after the operation, caused the fatigue on endeavoring to read to occur less quickly. Besides, it is easy to understand that when the musculus rectus internus was cut through, stronger tension of the accommodation, with convergence of the visual lines to a certain point, became possible." Can it be possible that Donders also does not know the difference between insufficiency and strabismus? Donders then refers to Bonnet, "for whom the priority of the application of the division of the muscles in these cases is claimed." Bonnet's work appeared in and about 1841. Thus we see that cutting of the internus where there was no strabismus is at least some fifty years old.

Now as to the detection and treatment of insufficiency of the externi. In a paper written some twenty years ago (1868) the writer dwells at some length upon the existence of insufficiency of the externi, and declares that it may depend upon three causes:

"1. Through an abnormal preponderance of either volume or force of the interni over the externi recti muscles, which may in themselves be below the normal standard.

"2. From faulty insertion of the muscles themselves.

"3. From a state of debility, either temporary or permanent."

Furthermore, a division is made into "actual and apparent insufficiency"—"actual where the weakness is inherent to the muscles themselves, apparent where it is due entirely to the efforts of the accommodation to overcome the error of refraction."[2]

In the same paper, p. 114 (1868), it is stated: "This fact led Giraud Teulon to express the belief that there was the same inherent tendency in hypermetropic eyes toward weak externi that there was in myopic eyes toward weak interni."

Also, "that in non-squinting hypermetropic eyes (under certain conditions) there is an absolute insufficiency of the externi, which shows itself the minute the colored glass is placed over one eye by homonymous images."

In another paper, written the same year, there is rather a lengthy discussion of insufficiency of the externi, with five cases, in which it is expressly stated there is no strabismus, and no double vision unless it was produced artificially by the colored glass. And here I stop to remark, by the way, that occasional double vision, where the images separate for a moment and then coalesce, is one of the surest signs of insufficiency that can be had. And I should also like to add, what is indeed well known to most oculists, that the colored glass, by reducing the instigation toward binocular single vision, will invariably bring out an insufficiency of the externi, if of a high degree, without the use of the prism; and that when it does, it is the surest test we have, for the reason that it does not produce a displacement of the images, but only reduces the instigation toward binocular single vision.

---

[1] Accommodation and Refraction, p. 273. 1864.

[2] Transactions of the American Ophthalmological Society, p. 115 et al. 1868.

In 1869 the writer again returned to the subject, in a paper entitled "Relative Accommodation in Strabismus and Insufficiency of the Recti Muscles," and insufficiency of the externi are treated of in emmetropia, hypermetropia, and myopia. It is very evident that Dr. Stevens has never read Donders, or Bonnet, or Guerin, or Philips, or, indeed, even my own three papers just cited.

It is in this last paper that the case was reported as having been operated upon as a case of "insufficiency of the externi," but which Dr. Stevens says was not a case of insufficiency of the externi, but a case of strabismus, because the patient had homonymous images at twenty feet, and diplopia, which continued up to eight inches. Dr. Stevens forgets to state that the diplopia was produced under a colored glass and a prism. This omission is not, I think, wilful, but simply because Dr. Stevens is not very well acquainted with the physiological principles of binocular vision, and the effect upon it of the colored glass. I cannot otherwise account for this suppression of facts. Neither Graefe nor anybody else would have called it anything but a case, exaggerated if you will, of insufficiency of the externi.

Here is another one just like it, but of less degree. L. T——, has 18° of insufficiency under colored glass at twenty feet; images do not coalesce until the candle reaches six inches. Without my knowledge the patient saw Dr. Noyes for another opinion. Dr. Noyes informs me by letter, "the muscular conditions are pre-eminently those of insufficiency of the externi."

But besides the cases related there is this general statement in the same paper, in relation to insufficiency of the externi, to the effect that, "if a marked degree of insufficiency of abduction is shown, a tenotomy is, in my opinion, not only justifiable, but necessary, notwithstanding the fact that no actual strabismus exists." [1]

In the face of this, and all that has preceded it, Dr. Stevens declares, "the first notices of cases of treatment of insufficiency of the externi, in which no strabismus existed, and in which important results were obtained, were reported by myself in various papers, from 1876 forward." [2] That is to say, eight years after my own publication, ten years after Pagenstecher, and forty years after Bonnet and his colleagues divided the interni for preponderance of power over the externi in cases in which there was no strabismus. It is simply impossible to argue against such statements, and I will leave this matter here.

It would appear to me that Dr. Stevens is wrong in regard to my accusing him of want or originality. It was rather that I thought he had been unjust to the illustrious Graefe and others; for instance, every one of the tests for insufficiency are von Graefe's which are mentioned in Dr. Stevens' work, together with the measurement of the adduction and abduction of the muscles, and yet Graefe's name is connected with only one of them, and that in its oldest form. In regard to my own want of originality I have no objection to make, for an elementary text-book must be, perforce, about "as original as wind in bellows," as Lowell has it. As a matter of fact, however, in regard to the colored drawings, there are fourteen of them, all told. Seven of these are original with the book, four are Jaeger's, and three are Liebreich's. I am free to confess, moreover, that if I could have found among the drawings of these masters, ones that were suitable for the particular points I wished to illustrate, there would not have been a single one of my own among the entire lot. It is not the newest of a kind, but the best of a kind that a student wants, and should have. As all the foreign ones are accredited to their rightful authors, and as my own are unsigned, I can easily see how, to those not very conversant with ophthalmic literature, the drawings should appear to be all foreign.

Yours truly,
E. G. LORING.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 19 *to March* 3, 1888.

VOLLUM, EDWARD P., Lieutenant-Colonel and Surgeon. Granted leave of absence for four months, with permission to go beyond sea and to apply for an extension of two months. S. O. 41, A. G. O., February 20, 1888.

GARDNER, E. F., Captain and Assistant Surgeon. Granted leave of absence for one month and twenty-one days. S. O. 41, A. G. O., February 20, 1888.

APPOINTMENT.

SHILLOCK, PAUL, to be Assistant Surgeon, with the rank of First Lieutenant. January 31, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 3, 1888.

HEYL, T. C., Surgeon. Orders to the receiving ship St. Louis revoked.

WHITE, C. H., Surgeon. Present duty continued to October 1, 1888.

STREETS, T. H., Surgeon. Ordered to the receiving ship St. Louis.

DRENNAN, M. C., Surgeon. Ordered to the receiving ship Vermont.

BRUSH, G. R., Surgeon. Detached from the receiving ship Vermont, and ordered to the Pensacola.

MEANS, V. C. V., Passed Assistant Surgeon. Detached from Naval Hospital, New York, and ordered to the Pensacola.

HOEHLING, A. A., Medical Inspector. Detached from the Pensacola, and wait orders.

HARMON, G. E. H., Passed Assistant Surgeon. Detached from the Pensacola, and wait orders.

EDGAR, J. M., Passed Assistant Surgeon. Detached from the Pensacola, and wait orders.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 3, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	3
Scarlet fever	151	25
Cerebro-spinal meningitis	8	6
Measles	63	6
Diphtheria	149	41
Small-pox	7	0
Yellow fever	0	0
Cholera	0	0

THE CAUSE AND CURE OF ABNORMAL SEXUAL DESIRE.—A philosophical and ascetic writer in the *Medical Standard* says the following regarding abnormal sexual desire: "In the great majority of cases sexual desire, which cannot be healthily controlled by the will, is due either to constipation, improper food, improper clothing, improper literature, ascarides, leucorrhœa, or analogous causes. Satisfaction of sexual desire will not remove these causes. Until they are removed the satisfaction of it in any way is but adding fuel to the flame. The results of so-called sexual starvation are due to partial sexual gratification in an abnormal, albeit unconscious, way, not to abstinence from sexual intercourse, and are cured by it. Cold sponging, proper diet, proper clothing, proper literature, and proper attention to the rectum will cure all cases of sexual starvation, except such as are reversions to the savage type of unrestrained debauchery, or depend upon cerebral or spinal disease or malformation. In the first case, training is indicated, and in the last, hospital treatment, not marriage or sexual intercourse. Christianity teaches restraint of the 'old man Adam.' Evolutionary ethics teach that the higher the organism, the better developed and the greater the checks on the primitive instincts of the race. Where theology, the dominant philosophy, and clinical experience join in condemning a procedure of doubtful morality intended to benefit one individual at the possible expense of another, the physician incurs a great responsibility who prescribes it."

[2] Functional Nervous Diseases, p. 207.

New Bandage for the Eye.—Dr. Wolfberg recommends a new material for use as a bandage in cases of ophthalmic disease. It is made by Eugen Müller, of Düsseldorf, who has named it "Hydrophilous Paper for Eye Bandages." It consists of linen and cotton wool, made in the form of paper, and impregnated with twenty-eight per cent. of glycerine. When used it should be saturated with a disinfecting fluid, squeezed, and then placed over the eye, wet wool being applied as an external dressing.—*Zehender's Zeitschrift*, September, 1887.

The Society of St. Luke, St. Cosmos, and St. Damien held its annual reunion in Paris, on October 17th last. There was a large attendance of physicians and students. On the first day several scientific papers were read and discussed, and on the second day, which was the feast of St. Luke, the members attended mass in a body at the Church of the Sacred Heart at Montmartre. The associate members of the Society at Lille also held a reunion at the same time. The Society is composed of French physicians who hold to the truths of Christianity, and its object is to oppose the spread of infidelity among the physicians, and especially the medical students, of France.

Gouty Urethritis.—Gouty urethritis is a disease the existence of which is not by any means universally admitted, but, in a thesis published in Paris by M. Turbure, some observations are made which claim attention. The discharge, he states, in gouty urethritis appears suddenly, and is abundant, and at first thick. Its color and nature is that of ordinary gonorrhœa at the acutest period. The pus is yellowish green, and it gradually diminishes in quantity and consistency, until it disappears. The functional symptoms which accompany this urethritis are said to be almost negative. The inflammatory reaction is *nil*, there is no redness, and no swelling of the meatus. No pain is caused during micturition, and no burning sensation is noticeable in the urethra. In some cases, however, there is more or less complaint of pain. The prognosis is generally favorable, because, in the opinion of the author, general treatment is all that is necessary to bring about a good result.—*Medical Press.*

Nutrient Enemata.—Physicians will generally indorse the conclusions of Professor Ewald, of Berlin, who has recently made some experiments with different nutrient enemata, and has found that enemata of eggs were of decided service, and that they were as efficient and satisfactory without being peptonized as when they were subjected to this process.

Masturbation in Women and Girls.—The vice of masturbation is far from being limited to the male sex. The ancients designated female masturbators as *tribades* (*tribein*, to rub), and the Lesbian women from the time of Sappho, that ancient erotic woman, had the reputation of solitary sacrifice to Venus. There is evidence that phalli of wax or of wood were offered publicly for sale among the Romans, as now among the Chinese. That the odious practice has come down to modern times is also evident enough, and more than one romance of our day has called attention to the prevalence of the solitary vice (tribadism) among women. Instances of each of the three following forms of masturbation frequently come under the notice of the physician: vaginal, clitoridian, urethral. Of these three forms, the clitoridian (simple titillation or friction of the clitoris by the hand) is the most common. Peculiar movements of the body, often calculated for this end, may accomplish the same titillation of the clitoris ending in voluptuous spasm. In one large tailoring establishment Pouillet found a number of girls who had become addicted to masturbation by the use of the sewing-machine; they had learned the habit of sitting in such a posture that the motion of the feet on the treadle brought about a pleasurable friction of the clitoris by the thighs. A confirmed female masturbator will practise the vice by rubbing the genitals against the arm of a chair, the corner of a piece of furniture, or even by divers contortions of the body. Vaginal and urethral masturbation has sometimes resulted in the lodgement of foreign bodies in those passages, and the intervention of the surgeon to remove the foreign body has been necessary. Dupuytren in one instance extracted a *tin cup* from the vagina of a confirmed masturbator; and, in another, a needle-case, introduced into the urethra, was successfully removed, after being present in this canal for a month. The list of substances used for the purpose indicated is varied: from spools, needle-cases, bottles, glass cups, etc., in the vagina, to needles, ear-picks, pieces of wood, and hair-pins in the urethra. Confirmed victims of secret vice have been known even to provoke titillation of the uterus by hair-pins, pieces of reed, etc., as in an instance recorded in the *Journal de Médecine et de Chir.*, vol. xiv., p. 70.—*Medical and Surgical Reporter.*

The Seat of the Ano-vesical Centre.—A case observed by Professor Rosenthal, together with one by Kirchoff, seem to show that the ano-vesical centre is in the conus terminalis of the spinal cord.

Plaster-of-Paris in the Treatment of Club-foot.—Dr. Burrows, of Lindsay, Ontario, referring to the article by Dr. Post on this subject in a recent issue of The Medical Record, writes that he has for years been in the habit of encasing the foot in plaster-of-Paris immediately after operation. He reported in the *Canada Lancet*, in 1878, a case in which the plaster was applied the day following the operation, and since that time he has been accustomed to put on the splint immediately after the performance of tenotomy. In order to avoid the frequent renewal of the splint, he removes a small piece of it from over the internal malleolus, in talipes varus, and after bending the foot outward fills up the space with fresh plaster. The writer also uses a padding of cotton under the plaster, in order to allow for shrinkage and to protect the parts. In the case of a young child he employs the plaster-of-Paris alone without previous tenotomy.

The Eyes of School Children.—Dr. H. P. Allen, of Columbus, O., was appointed by the Board of Education, of that city, to examine the eyes of the children in the public schools, and the results of his examination are now published in the report of the Board for 1887. The examinations were made chiefly to determine the condition of vision of the children, and to find, in cases where vision was defective, the correcting-glasses. The number of children examined was 4,700, and of these 1,175 were found to have defective vision in one or both eyes, 936 of whom had trouble in two eyes. The prevalence of near-sightedness increased steadily from no per cent. in the primary schools to thirteen per cent. in boys, and seventeen per cent. in girls, in the senior class of the high school. And, according to the ages of the scholars, it increased from no per cent. at six years to eleven and three-tenths per cent. at seventeen years. Other defects were about equal in the different classes, showing them to be independent of increasing age and increasing demands upon the eyes. Of all the children who were found to require correcting-glasses, only about ten per cent. had them.

Original Articles.

THE TREATMENT OF FLAT-FOOT.[1]

By BERNARD ROTH, F.R.C.S.,

ENGLAND.

I am glad to be able to comply with the request of my friend Dr. Gibney, to contribute to a symposium on the treatment of flat-foot, especially as some of my views have materially altered since I wrote the article on this common deformity in "Heath's Dictionary of Practical Surgery," upward of two years ago.

Flat-foot may be defined as a falling down or giving way of the normal arch of the foot, which may be so slight as to escape notice, except from the discomfort it causes, or be so severe that the whole tarsus presents as great a convexity inward as it ought to present a concavity, with the foot so everted that the internal malleolus touches the ground, while the outer border of the foot is raised, with the sole directed outward, as in some cases of infantile paralysis.

Sir James Paget speaks of "the constant pain and weariness of the lower limbs associated with flat-foot. The feet are elongated, flat, low, without insteps; the heels are too little prominent, the plantar arches sunken, the ankles thick; the astragalus, navicular, and inner cuneiform bones are below their right level. The pains complained of are those of the muscles and tendons, which are habitually overworked in the task of keeping the body erect when its proper bearings on its supports are disturbed." I consider this description applies to a severe case not due to infantile paralysis. Pain and much deformity are not always associated together; growing boys and girls approaching puberty are frequently brought to me, complaining of severe pain in the insteps, whose feet exhibit scarcely any deformity. Again, the severest cases of deformity, those due to infantile paralysis, frequently have no pain or discomfort in the feet, although sensation is perfectly normal. Flat-foot is, therefore, a very general term, and requires some sort of clinical classification if surgeons are to come to any agreement on the proper treatment. I think the best classification is one I proposed some years ago, viz.: (1) Cases in which it is possible to restore the foot completely to the normal shape by passive manipulation, without any force exerted by the surgeon, or by making the patient stand with the heels raised; (2) cases where the tarsal bones have become more or less fixed in their displaced positions by shortened ligaments and tendons, osseous deformity of the articulating surfaces, and fibrous or osseous anchylosis, which require forcible manipulation under anæsthetics to restore more or less of a normal arch; (3) intermediate cases, in which a partial restoration of the tarsal arch is possible without "brisement forcé."

A few words must be devoted to the causation of flat-foot, to enable us to obtain a correct view of the proper treatment. Mr. Le Gros Clark says: "In reviewing the action of the various muscles around the foot, it is obvious that their attachment is designed to preserve the plantar arch; and that such healthy condition must depend in great measure on the evenly balanced action of those muscles upon their several attachments. Thus the peronei and tibial muscles antagonize each other, and the expanded insertions of two of them into the tarsal bones is very instrumental in preserving the transverse as well as the antero-posterior arch."

I find that all infants on commencing to walk are normally flat-footed, without any tarsal arch, whereas after they have stood and run about a few months, and the leg-muscles have become developed, a perfect arch is formed. I have several times been consulted by an anxious mother about her baby's feet, when the child begins to run alone, the normal absence of a tarsal arch being at first exaggerated by a pad of fat opposite the plantar aspect of the tarsus. I have always been able to reassure her, and to tell her that the feet would become arched in time and the adipose instep-pad disappear, and the result has proved my prognosis to be correct.

Anything that tends to weaken the general muscular system during years of growth will also predispose to flat-foot. Thus I find that out of every three cases of lateral curvature of the spine two suffer from flat-foot, and every other one severely so. Flat-foot is also intimately associated with knock-knee; the one may follow close on the other, or both deformities may arise simultaneously.

Injury or chronic disease of one leg, throwing extra work on the sound limb, is also apt to produce flat-foot in the latter.

Although the bones of the tarsus are apparently so well supported by their ligaments and the tendinous prolongation of the muscles inserted in the sole, yet, as soon as these muscles shirk their work, from weakness or paralysis, undue strain is thrown upon the tarsal ligaments and they gradually yield, accompanied by more or less aching and pain, or none at all, according to the idiosyncrasy of the sufferer. At first there is no osseous malformation, and, so long as this is so, more or less complete restoration to the normal is possible; but in time the articulating surfaces become altered in shape, the bones distorted, and the ligaments so shortened and thickened that, even with extreme "brisement forcé," under anæsthetics, only a partial improvement is brought about. Indeed, the production of osseous deformity of the feet is caused in exactly the same way as is that of knock-knee. Flat-foot is therefore directly due to the weakness of the leg-muscles which are attached to the bones of the feet.

In the *treatment* of flat-foot we have to aim at the restoration and maintenance of the previously depressed plantar arch and the strengthening of the leg-muscles which tend to produce and preserve the normal arch of the foot. We have therefore to discuss (*A*) mechanical means for replacing and keeping up the plantar arch, and (*B*) therapeutic methods for strengthening the weak tibial muscles.

(*A*) In groups (1) and (3) a boot or shoe should be worn broad enough across the metatarso-phalangal articulations, best made from a tracing of the stockinged foot; and, if the toes are much deformed or displaced, the stocking should be digitated and the toes well spread out on the ground. The heel of the boot should be low and broad, not more than double the thickness of the sole in front. For raising the depressed arch I have employed for many years a pad made of superimposed layers of felt, and this, combined with treatment for improving the muscular power, has had good results; every now and then, however, a case proved very obstinate. For the last eighteen months I have discarded pads altogether, and I no longer insist upon laced-up boots being worn; indeed, the more freedom left to the movements of the ankle the better, and I therefore allow shoes to be worn when desired.

---

[1] Read at the Meeting of the New York Academy of Medicine, March 1, 1888.

Instead of a pad which, if efficient, tends to bruise and irritate the already tender tarsus, I employ an increased thickening of the sole opposite the ball of the great toe, and on the inner margin of the heel, according to the method of my friend Mr. H. O. Thomas, of Liverpool. His theory of the mechanical production of flat-foot appears to me to be the most rational; it is that in the normally constructed foot the lower end of the tibia is placed too much toward the inner border of the foot, so that the tendency of the tarsal arch is to give way under the pressure of the weight of the body, and has to be constantly combated by the efforts of the strong leg-muscles inserted into the foot. If we had to create a new foot and leg, simply with the view of preventing flat-foot, we should plant the lower end of the tibia rather more toward the outer margin of the foot. The device of the wedge-shaped sole, with the base inside and the apex outside, tilts or rotates the foot on its longitudinal or antero-posterior axis and carries the lower end of the tibia toward the outer margin of the foot, and thus removes all or most of the pressure of the weight of the body as transmitted through the lower end of the tibia from over the tarsal arch, in the same way as in the imaginary newly created foot and leg. The increased thickness of sole is from one-fourth to one-half inch, according to the severity of the case; an addition of a corresponding one-fourth or one-half inch is added to the inner margin of the heel, and this thickness gradually diminishes to nothing at the outer margin, which should be protected by a thin plate of iron or steel studs to prevent further differences of level of the two halves of the heel from wear. The same remarks apply to the increased thickness of the sole, which gradually tapers to nothing at the tip of the sole, as well as at its outer margin. This wedge-sole can be applied to boots already worn, and is equally efficacious applied to shoes. I believe that the benefit obtained by valgus-pads under the depressed instep is really due to the patient being forced to walk on the outer border of the foot to avoid the discomfort and annoyance of the pad pressing against the tarsal arch. Boots made, and so much advertised, with movable or spring-like waists are useless, and even injurious if the spring is prolonged to the outer margin of the sole, where the foot ought to rest entirely on the ground. As the chief movement in walking is at the metatarso-phalangal articulations, it would be an advantage if this portion of the sole could be made of a more yielding leather.

In group (2), where the displaced arch cannot be replaced except by "brisement forcé," I would recommend this being effected by Mr. H. O. Thomas' club-foot wrench, under anæsthetics, and the foot kept in a suitable splint in the improved position till all symptoms of the traumatism have disappeared, and the patient then treated as in groups (1) and (3).

(*B*) Therapeutical methods for strengthening the weak tibial muscles: I know of no better exercise than walking on the toes with the heels raised an inch or so, taking care that they are not raised too much, for when the longitudinal or long axis of the foot behind the metatarso phalangal articulation is raised too vertically there is less work for the muscles, as much of the weight of the body is transmitted directly through the bones of the tarsus and metatarsus standing on end.

It is a good plan to order the patient to walk fifty steps on the toes before and after each meal.

The chief "medical gymnastic" exercises I employ are the two following: (a) is "sitting, foot inward circumduction, repeated forty times." The patient, sitting on the floor or couch, with the back supported and the knees extended, circumducts the foot down, in, up, and out, while the toes are directed inward the whole time; the knee and hip should be kept perfectly still. The leg should rest on a small pad just above the tendo Achillis, to leave the foot free. (b) is "sitting, foot adduction (surgeon resisting) and abduction (patient resisting)," repeated twenty times. The patient is placed in the same position as before; the surgeon fixes the leg just above the ankle with one hand, while the palm of the other exerts a gradually yielding resistance to the patient's effort to adduct and invert the foot. On the completion of the adduction the patient strives to maintain this position of the foot while gradually yielding to the pressure of the surgeon's hand gently pushing the foot back to the commencing position.

I sometimes employ another exercise, viz., walking on the outside edges of the feet with the soles directed inward and forward. Patients with flat feet will frequently assume this last position instinctively, to give relief to the overstrained ligaments of a displaced tarsus.

In cases of extreme weakness of the leg-muscles, rubbing (massage) of the leg-muscles for half an hour, once or twice daily, should be employed; for the technique, I can only refer those interested to my article "Massage" in "Heath's Dictionary of Practical Surgery."

Necessarily in cases of infantile paralysis, where the muscles have completely wasted, only the mechanical portion of the above treatment can be carried out, with the addition of an elevating spiral steel spring to lift up the foot, for clearing the ground during walking, if there is foot-drop.

In all cases due attention should be paid to the general health, and to the removal of all debilitating causes.

Such severe treatment as the removal of a wedge-shaped piece of bone from the tarsal arch, under antiseptics, does not appear justifiable, and I have not yet seen a case which offered any reasonable probability of this treatment being of permanent benefit to the mutilated patient.

The effects of the treatment I advocate begin to be felt within a week or two by the patient, and I seldom see cases where all pain and discomfort have not disappeared within three or four weeks, some even within a few days. For the cure of the deformity, even slight cases require several months, and for severe cases I generally find that a year or more of perseverance with the boots and treatment are necessary.

I append a typical case, illustrating the treatment above described.

Mrs. ——, wife of a member of the British Parliament, consulted me, July 7, 1884, with the following history: Two years ago she began to have discomfort in the feet after walking—"a feeling as if the ankles were too soft." The discomfort increased for six months, when she became a vegetarian, and, for a time, the pain in the feet was less. Since then the pain has become gradually worse up to the present. The patient is an active, extremely intellectual woman, fairly well nourished; menses still quite regular, but inclined to be rather profuse; she can only walk up and down stairs, or a few yards out of doors, and that with considerable discomfort. I found both feet severely flat (intermediate, or group (3)), with the pain and aching just under the arch of the instep, and described as "a dull, aching soreness" which becomes acute pain at times; standing causes even more pain than walking. On August 25th, viz., *six weeks* later, patient wrote: "I am following your prescription as far as I can, and feel much better." Again, on November 18th, four months later: "I am a great deal better. . . . I have worn the boots, and, though painful at first [I employed pads at that time], I find now that they give me the greatest support. . . . I must thank you most heartily. . . . When I was in London I was trying to school my impatience to resignation to a walk of not more than a hundred yards at a time; now I can walk two miles without much fatigue, and am astonished at the elasticity and youthfulness of my movements. I consider myself a walking advertisement of your surgical capacity!" This lady has continued well up to the present time.

Chlor-anæmia.—This condition—deficiency of hæmoglobin in the blood—Dr. R. C. Hutton considers pathognomonic of endo-cervicitis, arriving at this conclusion after carefully examining forty cases. A notable and important fact is that, in cases of chlorosis or chlor-anæmia, the system never responds, in any appreciable degree, to the effect of tonic or restorative medicines until the local conditions are changed.—*Post-Graduate.*

A FURTHER CONTRIBUTION ON LOCAL MEDICATION OF THE SPINAL CORD, WITH CASES.[1]

By J. LEONARD CORNING, M.D.,

NEW YORK.

SOME time ago, in an article published in the New York *Medical Journal* for October 31, 1885, I showed that when a given amount of a medicament is injected into the vicinity of the spinal cord certain modifications in the functions of the latter may be induced.

Thus, when strychnine is injected in this manner, the functions of the cord, and notably the reflexes, are greatly exalted; much more so, in fact, than if the medicament had been simply injected into the general circulation, as in ordinary hypodermic medication. On the other hand, the modifications in function which I observed after injection of an anæsthetic, such as cocaine, were sensory in character—such, for example, as more or less complete anæsthesia, tingling, numbness, and various other paræsthesia, these phenomena being principally confined to the parts below the point of injection. The line of argument which led up to these results it is not necessary for me to detail on this occasion; enough, that the experiments, which were at first conducted on dogs, were afterward verified in man; and the expedient has since been resorted to on several occasions. I was careful, too, to point out that this principle of medication offered an admirable and heretofore unsuspected and potent means of treating certain derangements of the spinal cord. Thus, it was shown that the painful phenomena which are present in spinal irritation may be combated by resort to this exceedingly direct and effective therapeutic procedure; and to this I may add that the permanency of the effects produced are enhanced by the combination of cocaine with other remedies.

Having ascertained this much, it occurred to me that it would be a matter of practical interest to pursue these researches further; accordingly, shortly after the publication of the paper above referred to, I conducted the following experiments:

1. I injected a solution of sulphate of strychnine under the skin of a rabbit in sufficient quantity to induce general convulsions. I then injected a quarter of a grain of hydrochlorate of cocaine subcutaneously, but without modifying in the slightest degree the convulsive phenomena; in a word, I may state that I continued to inject this drug (hydrochlorate of cocaine) until well-marked toxic symptoms had been developed, but was not successful in modifying the convulsions to the slightest extent. The results thus obtained are directly at variance with those recorded by certain recent German observers.

2. In this experiment I again induced the convulsions by subcutaneous injections of the sulphate of strychnine, but instead of injecting the cocaine under the skin of the animal, I injected ten minims of the four-per-cent. solution *between the spinous processes of the vertebræ.* The first injection was not followed by any marked reduction in the tetanic symptoms for several minutes; therefore, at the end of ten minutes I injected the same quantity as before, except that it was distributed in several intervertebral spaces. After the lapse of about fifteen minutes from the first injection the severity of the convulsions had markedly decreased, and the animal could be handled without their induction.

From the first experiment, therefore, it is clear that the injection of cocaine preparations into the general circulation, even in large quantities, is not sufficient to counteract the toxic effects of strychnine. Experiment shows, on the other hand, that when the drug is brought in a concentrated form into the immediate vicinity of the cord the reflex phenomena may be markedly diminished, provided, of course, that a too large quantity of strychnine has not been taken. When we consider how much greater the local than the general action of the drug is, this disparity of effect is easily accounted for. But it is in the painful affections of the cord, such as ataxia, that I believe we shall attain notable results by resorting to this direct method of medication. So convinced have I become of the necessity of making some radical departure in our mode of attacking these painful maladies, that when I had observed the phenomena recorded in my first paper,[1] I resolved, as soon as an opportunity should present, to test this local medication in the painful affections of the cord. There was one obstacle to the execution of these plans, however, which puzzled me for a long time. Briefly stated, the problem in question is this: How is the physician to know how far he may thrust the hollow needle, used in transmitting the medicament from the syringe to the vicinity of the cord, without danger of wounding the latter?

As I have said, this problem puzzled me for a long time; and yet there was no evading it, for I saw at once that if the procedure were to prove effective it could only be by depositing the medicinal substance as close to the cord as possible. There are not many problems in this life, however, which cannot be solved by hard and properly directed thinking, and this one proved no exception to the rule. To make a long story short, I succeeded completely; and this is how the matter was accomplished. Having examined the vertebræ of the lower portion of the spinal column, I observed that the posterior surface of the transverse process, even at its greatest depression, though almost on a level with the posterior aspect of the foramen vertebræ, did not fall at all, or, in rare cases, possibly very slightly below it. This is especially true of the ninth, tenth, eleventh, and twelfth dorsal, and of the first and second lumbar vertebræ. As soon as I had observed this anatomical coincidence, I saw at once that, in so far as the lower vertebræ were concerned, the problem of approaching the immediate vicinity of the cord with the point of a hypodermic needle, without danger of wounding it was solved. In a word, to make the matter short, the simple technique which I elaborated on the basis of these observations is as follows:

1. I first, as a rule, induce a condition of cutaneous anæsthesia in the vicinity of the spinous processes of the tenth and eleventh dorsal vertebræ almost as large as a silver dollar. This I do simply for the comfort of the patient and for no other purpose. The electro-chemical method[2] elaborated by me, or the hypodermic syringe, may be employed for the purpose.

2. I now call into requisition a fine needle, about three inches long, provided with a handle and a sliding nut (Fig. 1). The latter may be fixed at any portion of the continuity of the needle by means of the screw. This needle I thrust down (about half an inch laterally from the spinous process of the tenth dorsal vertebræ) until the bone is reached. The nut is then pushed down till it rests lightly upon the skin, and is secured in place by means of the screw (Fig. 2). I then withdraw the needle.

It is now clear, from what has already been said, that the distance from the nut to the point of the needle corresponds almost exactly with the distance from the surface of the integument to the cord. To make assurance doubly sure, however, I am in the habit of subtracting two or three millimetres from the measurement thus attained.

3. Upon a fine cannula (Fig. 3), likewise provided with a sliding nut, the distance previously noted upon the needle is measured off (minus two or three millimetres), and the nut secured firmly in place.

4. This hollow needle is then attached to a syringe (Fig. 4) of one hundred minims capacity, filled with a one-and-a-half-per-cent. solution of the hydrochlorate of co-

---

[2] See the New York Medical Journal for November 6, 1886.

caine, to which is added about gr. $\frac{1}{75}$ of pyrogallic acid. I have used solutions of various strengths, but am inclined to give preference to those of one-and-a-half per cent.

5. The cannula is now thrust into the tissue between the spinous processes of the tenth and eleventh dorsal vertebræ (I have sometimes inserted it between the ninth and tenth) until the nut, previously firmly fixed as described, rests upon the integument.[1] The contents of the syringe are now slowly emptied, and the needle withdrawn.

6. The patient should now be allowed to lie on his abdomen, with his legs hanging over the edge of the sofa or bed in such wise as to put the dorsal muscles on the stretch. This manœuvre presses the fluid in the direction of the least resistance, *i.e.*, the cord, besides causing the rigid muscles to act in a certain sense as an incarcerating mechanism; that is to say, that in their rigid condition they prevent the medicament, to some extent, from being absorbed by the tissues outside of the spinal canal. Of course, when the solution has once entered the spinal canal, we can do nothing to keep it in permanent contact with the latter. The circulation at the lower segments of the cord is, however, as is well known, extremely lethargic, so that the solution cannot be washed away very rapidly. This torpid state of the circulation, already alluded to by Brown-Séquard in his papers on paraplegia, no doubt accounts for the persistence of numbness and anæsthesia more or less profound after the injections have been made.

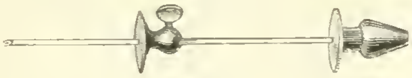

FIG. 1..

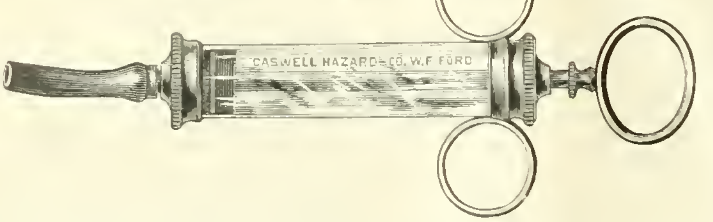
FIG. 4..



So much, then, for the technique of this mode of treatment. Relatively long as is necessarily the description, the execution of the manipulations themselves is by no means so difficult as might be imagined. I have employed the procedure many times, sometimes using cocaine alone, and sometimes combined with the tincture of aconite or pyrogallic acid, according to the effects which it is desired to obtain.

In the affection commonly known as spinal irritation, whether there be a condition of congestion or anæmia I care not, its effects are certainly in the highest degree beneficial, as I have already had occasion to demonstrate to my entire satisfaction in several cases. How much may be obtained in inflammatory affections of the cord only an extended experience can, of course, determine. In purely functional derangements, however, its efficacy is beyond question.

The following brief synopsis of cases will serve to exhibit the promptness and permanency of the effects often obtainable by resort to this mode of treatment.

1. Mrs. C——, a young married lady, consulted me some months since on account of severe pains between the shoulders and at the back of the neck. These pains were exceedingly persistent. They were readily evoked by slight exertion, such as bending forward, walking, or lifting small objects, and they had failed to yield to any sort of treatment whatsoever. Previous to consulting me, this good lady had submitted to an ordeal in the way of treatment which was as unique as it was ineffectual. Her back had been cauterized repeatedly; she had been plied with all manner of drugs, so that her stomach was in an exceedingly bad condition; and last, but not least, her vagina had been bedouched, besalved, and bestuffed, according to the most exacting tenets of modern uteromania. It was natural, in the face of all this, that the mind of the patient should have become somewhat hypochondriacal; and it was equally to be anticipated that her morbid reflections would centre upon the pelvic organs; so that when, during consultation, she asked me, with considerable trepidation, whether I did not believe that she "had better have her womb cut out to cure the pain in her back," I was not inordinately astonished.

An examination of the spine revealed three exceedingly tender points at the upper and middle dorsal region. At two of these points pain was at once induced by pressure, at the third spot it could only be evoked by the application of the electric brush.

Such being about the condition of affairs, I decided, with the patient's full concurrence, to try the effect of local medication at the seat of pain.

Having filled the large glass syringe already referred to with a solution containing gr. $\frac{1}{75}$ of pyrogallic acid and one-and-a-half grain of cocaine to one hundred minims of water, I injected the entire contents of the syringe (one hundred minims) into the upper painful spot. Ten minutes later there was no pain at the point of injection; and what, at the time, seemed still more remarkable to me, the tenderness had entirely disappeared from the painful spots below the point of injection. As I now look at it, I am inclined to ascribe this striking phenomenon to the gradual deportation of the anæsthetic into the regions below the point of introduction. This explanation would seem to accord well with what we know of the distribution of the blood-vessels in the spinal canal; but I will not incur the danger of wearying you by further speculations on this point.

Enough that after this single injection the patient was able to execute all kinds of movements, such as bending forward, lifting objects from the floor, and the like, without the slightest pain. This exemption from suffering continued during the eleven following days, when having, as she thought, exposed herself to the effects of cold while riding in a horse-car, there was a return of severe pain. I again made an injection as before, selecting for the purpose the region about the second painful spot. A like happy issue was the result, complete abolition of pain, an

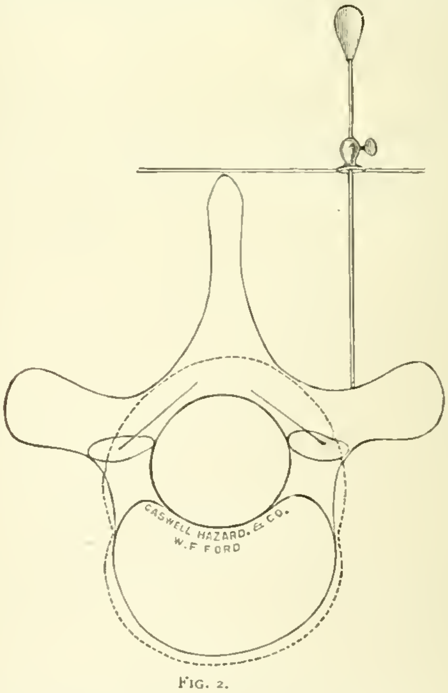


FIG. 2.

---

[1] When the injections are made in the upper and middle dorsal regions the precautions detailed above are not so necessary, though, perhaps, on the whole, they are preferable.

exemption which has continued, so far as I know, up to date.

2. Neurotic youth of sixteen. Has been addicted to masturbation for some years, a habit which he says he acquired at school. His parents, however, insist that he was addicted to the practice before going to school. That as it may be, there is pretty good evidence that he has masturbated more or less since his tenth year.

Six months ago I was consulted by the parents of the boy on account of a severe pain located at the lower portion of the back. On examination tenderness on pressure was found at the eighth dorsal and tenth lumbar vertebræ. When the patient attempted to bend forward the pain evoked was quite acute. Of late he has been able to indulge in walking but little, owing to the painful sensations to which it, as well as all forms of exercise, gives rise. Is sleepless, irritable, and depressed.

Most of the conventional remedies having been tried without avail in his case, I determined, his parents readily consenting, to try the efficacy of local medication. Accordingly, I injected seventy-five minims of an aqueous solution containing gr. $\frac{1}{75}$ of pyrogallic acid, and gr. $1\frac{1}{2}$ of cocaine at each point of tenderness.

In ten minutes the patient could execute all kinds of bodily contortions, such as bending forward, laterally, and even backward.

The relief lasted for hours, and, indeed, for the next four days there was marked improvement. At the end of that time, however, the local tenderness again appearing, if anything, in a more aggravated form than at first, I again made the injections precisely as before, and with the same results, except that the effects were altogether more permanent, lasting for the following three or four weeks. A slight degree of tenderness then made its appearance, and, strange to relate, at a point higher up. An injection was at once made at the painful point, resulting, as usual, in complete abolition of all tenderness. Several months having now elapsed and no complaint having been made, except on account of occasional cutaneous hyperæsthesia, which is as usual relieved by a strip of ordinary belladonna plaster, I think that we are perhaps justified in looking upon the case as practically cured.

3. A young man, twenty-two years of age, was referred to me some time since by Dr. L. Bolton Bangs. Briefly, the patient had been operated upon for stricture by Dr. Bangs, and six days afterward developed severe spinal irritation.

More or less dull pain was felt in the lumbar region and sacrum, extending to the lower dorsal vertebræ. At the seventh dorsal vertebra pain on pressure was exceedingly acute; and from this point intercostal pains of great intensity, particularly on the left side, were radiated, so that breathing was shallow and accompanied by much distress.

Dr. Bangs had recourse to large doses of ergot, and applied the actual cautery to the back of the patient in a most thorough manner. Still, though there was apparently some amelioration, it was felt that the relief experienced was far from satisfactory.

Accordingly, Dr. Bangs, being cognizant of my interest in local medication of the cord, requested me to ascertain whether the severe pains, and particularly those about the chest, could not be relieved by local means.

Appreciating the necessity of affording as speedy relief as possible, I at once injected one hundred minims of an aqueous solution containing about one-sixtieth of a grain of pyrogallic acid, and one grain of cocaine, into the painful zone in the immediate vicinity of the seventh dorsal vertebra.

Ten minutes after the injection had been made, patient experienced complete relief from the intercostal pains. He could bend the body from right to left, backward and forward, and inflate his lungs to their fullest capacity without the semblance of pain. Pressure upon the seventh dorsal vertebra also failed to evoke the slightest sensation of discomfort. During the following two hours patient remained in my office, and at the end of that time, there being no sign of returning discomfort, I allowed him to walk home unattended. Three days later he again reported at my office, and, though an examination of his spine revealed some superficial soreness, the deep-seated pains were not evoked, nor had there been any return of the intercostal pains. For the relief of the cutaneous soreness the simple application of a strip of belladonna plaster was found sufficient.

The subsequent course of the case presents some interesting genito-urinary features, which I trust at some future date Dr. Bangs will elucidate with his accustomed skill. As for the spinal irritation, I feel that a cure has been practically effected, although the severe changes in temperature experienced during the last few weeks have evoked at times a slight return of soreness. This soreness has been easily controlled by moderate doses of antipyrine.

4. Old case of spinal concussion in a gentleman of fifty, who met with a railway accident some years ago. Has been under my care for many months, and, although able to dispel the psychical depression from which he has long been a sufferer, I was, until recently, unable to abate a severe soreness at the region of the lower dorsal vertebræ. This soreness he ascribes to the fact that he was caught between two seats of the car on the occasion of the railway accident above referred to.

Having tried all the usual superficial local measures without success, I undertook, with the patient's consent, to abate the symptoms by resort to deep local medication. As in the previous cases, the injections were conducted at the seat of pain, with every precaution, and with the result of affording complete and immediate relief from the painful symptoms. Four days after the injections there was some slight return of soreness, but this was at once controlled by supplementary injections. Some weeks have now elapsed since the last injection was made and there has been no return of pain. I shall take the liberty of reporting more at length on the course of this case at some future time. Finally, I desire to thank the Society for the courteous attention with which they have listened to this somewhat long discourse—a recital, however, which I trust may prove not without practical result.

26 West Forty-seventh Street.

Gonorrhœal Peritonitis.—Dr. E. Ceppi, of Porrentruy, reports a case of chronic purulent peritonitis in a previously healthy and robust woman, aged twenty-nine, which was cured by abdominal incision and drainage. The disease proved to be of gonorrhœal origin, small accumulations of Neisser's gonococci being found in the pus-cells. Similar microbes were discovered also in the purulent discharge from the uterus. This case is said to be the first in which the gonococcus has been found in the peritonitic exudation.—*Revue Médicale de la Suisse Romande.*

Mental Derangements and Malaria.—From an inquiry into the relations existing between malaria and certain disorders of the mind, Drs. Lemoine and Chaumier have arrived at the following conclusions: Violent mania, without clearly defined characteristics, may accompany an attack of intermittent fever in predisposed persons. In the same class, but far less often, convalescence may be the starting-point of a mild form of insanity, stupor, or mania of uncertain duration. This is usually curable. Old subjects of malaria, with masked manifestations, are liable to recurrent intellectual disturbance, or to chronic insanity. The diagnosis of the latter is impossible without a full previous history of the patient. There probably exists a form of pseudo-general paralysis of a malarial origin. It is an important matter in treatment to ascertain the presence or not of intermittent fever as an etiological factor in the history of all cases of insanity. Quinine gives good results in intermittent mania and its convalescence. It is apparently of no value in the chronic cases, but even in these the drug may quiet transient attacks of agitation as if they were masked phenomena of the disease.—*Annales Medico-psychologiques.*

GANGRENE OF THE ISCHIO-RECTAL FOSSA—RECOVERY.

By ROBERT ABBE, M.D.,
ATTENDING SURGEON, ST. LUKE'S HOSPITAL, NEW YORK.

THERE is a rare and interesting form of acute inflammation of the contents of the ischio-rectal fossa which, while it resembles in some of its features the abscess-formation in this region which is so common and usually leads to fistula, yet differs, not only in its intensity, but in its progress and termination. It is very definitely termed an "idiopathic gangrenous cellulitis around the rectum." It is not mentioned in most surgeries, and no statistics have been gathered, because of its rarity. It usually occurs, as observed by Mr. Furneaux Jordan in 1879, in men of active habits who live well, drink freely, and go about regardless of the weather. It was also spoken of by Nunns (*Lancet*, 1866).

The seizure is usually sudden—some pain and restlessness in the rectum, perhaps a chill, malaise, and rapidly ensuing fever. Attention being drawn to the fundament, a brawny cellulitis is found on one side the bowel, an erythematous blush suffusing the buttock. It differs from the commencing abscess by being more diffused, and not pointing. It runs a rapid course, creeping, in upward and lateral directions, around the bowel, and has even extended to the gluteal regions. There is sometimes agonizing neuralgic pain, depending on whether the hard mass runs deeply and involves nerves of any size; pains not only local, but into the legs. The bowel-action may be paralyzed, and the bladder suffer from retention.

As early as the third day, though sometimes delayed to the fifth, there appears a black slough of the skin covering the fossa. This may be wanting in many cases, and then only the cellular tissue filling the fossa is found to be a black sloughy mass when the skin is incised.

One would expect to find pus on cutting into such a mass, but this is not the case. There is a darkish puriform fluid sometimes in the slough, as is met with in gangrene tissues, but no abscess, and, moreover, the malady does not eventuate in fistula.

The sloughy tissue comes away in time, if the patient survives the inflammation, which frequently he does not, and leaves a granulating wound which, when healed, leaves a surprisingly small cicatrix.

A disposition has been observed, in a few cases, to recurrence of the cellulitis before the wound heals; this is rare. Furneaux Jordan saw it in one of three cases he knew of, and as another sequel there occurred pleuro-pneumonia in the same man, from all which he recovered. These would be properly regarded as septic.

The etiology is uncertain. The patient may sometimes assign a cold, exposure, or a hard chair, or some other improbable cause, but the progress of the disease has a decidedly septic look, as much so as erysipelas. The author above mentioned likens its course, very properly, to the gangrenous cellulitis of the neck, or Ludwig's disease.

Two years ago I was asked by Dr. A. B. Campbell to see, in consultation with him, a typical example of this disease.

A man aged forty, in good health, a carpenter, was seized on Sunday, February 7th, with a chill, followed by fever and restlessness about the bowel; no pain.

On Monday, pain was severe at the coccyx, in the fundament, and down the back of both thighs. He evacuated his bladder all right, but on Tuesday and Wednesday his bladder filled up nearly to the umbilicus, and was evacuated by catheter. His bowels were confined.

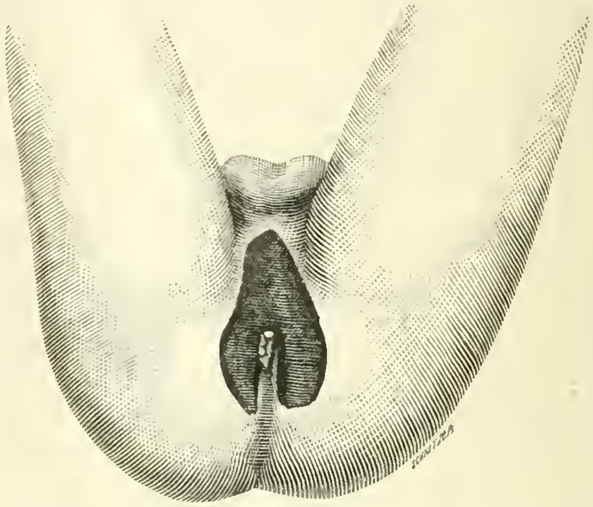
On Monday he took three compound cathartic pills; on Tuesday a bottle of citrate of magnesia and two Seidlitz powders; on Wednesday a whole bottle of Hunyadi Janos water; on Thursday an enema, which acted.

On Wednesday the erythema of the beginning gangrene extended from one tuber ischium to the other, surrounding the anus. By Saturday it had gangrened, and the entire space, as illustrated, was black. No swelling preceded the gangrene. By the following Tuesday the margins were well defined and the gangrene quite symmetrical.

The pain subsided, Thursday of the first week, and did not recur. The temperature reached 104° F. on the fourth day and declined to 102½° on the tenth day.

There were no more chills, nor did he sweat. He passed his urine voluntarily on the eighth, ninth, and tenth days, but atony came on again; yet the bladder gave him pain if partially full. The bowels also acted. There was no albumen or sugar in his urine. He had no strictures or leaking of urine, and no heart trouble to cause emboli.

We cleared away the gangrene, which amounted to sloughing of the entire cellular contents of the fossæ, leaving the deep perineal fascia naked, and the rectum a tube unsupported in this space, except by a neck of skin posteriorly. The gangrene stopped at the edge of the bowel, and no opening into it was ever found. Recovery was slow but perfect, and the patient has a good sphincteric control of the bowel.



In considering the possible causes of such an affection, one would think of diabetic gangrene, or Raynaud's disease, or an embolus, though it is hardly conceivable that plugging of the internal pudic or any vessel supplying the perineum could do damage which arterial anastomosis, so free here, could not repair. We must regard it, then, as a septic cellulitis in all probability, and congratulate ourselves that, if incised early, it tends to recovery.

It has lately occurred to me to see one other case of gangrene of the parts in this neighborhood, which I will briefly narrate, for its rarity and for contrast:

A lady, thirty-three years of age, had repeated peritonitis from suppurative salpingitis. In last October this caused a large pelvic abscess, which, after I had advised operation, opened spontaneously into the rectum. She was slightly phthisical, and was greatly exhausted by it all.

She picked up after evacuation, but soon declined again, and four days before death developed, in as sudden a time as twenty-four hours, a gangrenous area, an inch and a half in diameter, with a fecal fistula following later in its centre, and found on post-mortem to connect with a large extravasation of fæces into the abscess-sac of the pelvis. This had gone out of the aperture through which the pus evacuated into the bowel.

THE MIND AND THE HAIR.—Professor Pohl-Pincus has been studying the effect of emotions upon the physical and morphological condition of the hair. As an illustration of the proficiency which he claims to have obtained in detecting changes in the hair-roots, he states that, from a mere examination of the hair, he was able to point out as the cause of disease, in the case of a chaste young priest, a severe temptation which he had manfully withstood, but which had nevertheless caused a serious mental shock.

CHRONIC ATROPHIC SPINAL PARALYSIS IN CHILDREN.

By D. F. KINNIER, M.D.,

NEW YORK.

Of late years electro-diagnosis has materially aided in elucidating many disputed points in that form of paralysis known as "atrophic paralysis." Having carefully observed a few cases of this disease in the clinics of Professor A. Hughes Bennett, and at the Hospital for Paralysis and Epilepsy, Bloomsbury Square, London, I venture to offer a few remarks on this interesting form of paralysis.

This form of paralysis is characterized by a rapid wasting of the tissues, owing to degenerative atrophy of the muscles and of the nerves directly associated with these muscles.

Owing to the rarity of this disease, or, perhaps more correctly, failure to detect it, in children, I trust the few observations which I have made will be of interest in helping to a correct diagnosis of it, as well as to point out the peculiar electrical phenomena characteristic of this form of paralysis.

My first case is that of a child, three years of age, who always enjoyed good health until one year ago, at which period of his life he had a very severe attack of measles, recovery from which left him in a very weak physical condition. Two months after recovery from his illness the patient was not inclined to engage in his usual amusements, and some difficulty in his mode of progression was observable. When asked to stand he could hardly do so except with assistance, and usually wished to rest his hands on a chair or table if one were near by him. The limbs were weak and shaky, and he was in danger of falling if allowed to stand unprotected. His walk was very defective, owing to lack of co-ordination.

His cutaneous sensibility appeared to be normal, as tested by the æsthesiometer. The plantar reflexes were well marked, as were also the knee-jerks of both sides.

There was no rectal or vesical paralysis, but there was a marked atrophic condition of the extensor muscles of the forearms and hands. There was no apparent loss of bulk in the muscles of the lower extremities, but the circulation was sluggish and the local temperature was below normal.

Electrical reactions could not be determined with accuracy, owing to the irritability of the child.

A *faradic* current applied to the median nerves showed the reactions to be very much diminished on both sides, but, on the contrary, normal muscular contractions were observed when a like current was applied to the ulnar nerves, especially in the vicinity of their trunks. But the most noticeable failure of nerve-response to electrical stimuli was observed when the faradic current was applied to the musculo-spiral nerve near the elbow, at which point the strongest current failed to bring forth contractions in the muscles supplied by this nerve. The flexors of the forearm when stimulated gave rise to normal muscular contractions, but a negative result was obtained when a powerful current was applied to the extensor muscles of the forearm.

A very delicate point in the examination of this case was demonstrated when the faradic current was applied to the extensor indicis of the right and the extensor ulnaris of the left side. When a powerful current only was applied to these muscles there was produced a slight contraction, thus showing that there was not complete degenerative atrophy of these muscles.

The *galvanic* current was next applied to the ulnar and median nerves, giving rise to apparently normal contractions. A strong galvanic current when applied to the musculo-spiral nerves produced extension of the wrist and fingers, the ACC being more increased than the KCC. The ACC was decidedly increased when a strong galvanic current was applied to the flexors of the forearm, giving rise to vigorous contractions of these muscles.

Next turning our attention to the smaller muscles, namely, the extensor indicis of the right side and the extensor ulnaris of the left side, we found a difference of electrical reactions, as compared with the larger muscles referred to. While in the case of the flexors of the forearm powerful contractions were set up by galvanic stimulus, in the two smaller special extensor muscles the response to electrical stimulus was diminished, the contraction being slow and tonic, illustrated by the following: ACC > KCC, as distinguished from the effect of the current on the flexors, where the ACC was decidedly increased. These were the only extensors of the wrist and fingers which readily responded to the galvanic current. The muscles of the lower limbs responded readily to the electrical stimuli, as did also the nerves in the same region. I carefully watched the progress of this case while under observation, the patient having been kept in bed the greater part of the time, and galvanism was faithfully applied to the spine for a lengthened period. At the end of six months a decided improvement was effected and a favorable prognosis was given, which opinion proved, later, to be correct, as the child made a complete recovery.

Another case was observed in a child, five years of age, who had a neurotic family history. The patient had had measles and whooping-cough, but no other sickness of any account, and no trouble in walking till she was four years of age, when one day she came in from playing and complained of pain in her left foot and leg. No particular attention was paid to this matter, as it was thought the foot might have been slightly sprained. About two weeks after the child began to complain of these symptoms she was observed to slightly drag the left foot, which gradually became more marked, and like symptoms showed themselves, later, on the right side.

The case promising to be very interesting, a most careful examination was instituted. The disease evidently was slow and gradual in its onset, and paretical signs were now well marked.

When first seen the patient presented slight impairment of the functions of the bladder and rectum, but this slight paresis disappeared in a short time after treatment with the battery was begun. Both legs showed signs of paralysis; the child could not walk without assistance, and her gait was very unsteady and staggering. The muscles below the knee were evidently wasting; the knee-jerk and plantar reflexes were very much decreased; cremasteric response defective. Galvanism of the muscles gave rise to sluggish contractions, with the ACC less than the KCC.

A nice point in the diagnosis of this case was the demonstrating of partial reaction of degeneration, very well brought out when electrical stimulus was applied to the vicinity of the trunks of the peroneal nerves. Galvanism was applied three and four times a week to the paralyzed limbs, notwithstanding which the disease continued to advance, and three months later the patient was unable to walk. The child at this period, although being of fair physical constitution, yet had marked evidences of weakness of the lower limbs, with paralysis of the muscles in the tibial and peroneal regions. Sensation was intact, as tested by the æsthesiometer and pins, with the exception that when the two points of the æsthesiometer were separated by a distance of one-fourth to one-half an inch there was difficulty in detecting two distinct points of touch by the patient. The atrophy of the legs had increased to such a degree that the limbs were now distinctly wasted.

The following measurements of the legs were noted: Circumference of right thigh directly above the patella, 25 ctm.; left, 26 ctm.; circumference of right calf, 15 ctm.; left, 16 ctm. This case was carefully observed and treated, and signs of improvement began to show themselves at the end of six months; movements of both feet more pronounced, and there was also manifest a more ready response of the tibial muscles to electrical stimulation. Contractions of the muscles of the thigh, both extensor and flexor, more marked when stimulated than earlier in the disease. The circumference of the calf of the legs had now increased about 1 ctm. The patient continued to improve to such an extent that at the end of nine months the knee-jerk had to a considerable degree returned; movements of feet were also better, and the muscles were less flabby. The contractions were more active when irritated by electrical stimulus, as, for instance, sixteen cells, slow ACC; twenty cells, rapid KCC on right side. For the ensuing few months the patient was seen at irregular intervals, and at the end of one year, the disease in the meantime making continuous progressive improvement, the patient was subjected to a careful examination, when it was found that the faradic and galvanic stimulation called forth an almost normal response, except that there yet remained a little flaccidity of the muscles of the left leg, in which the electrical phenomena will no doubt return to their normal condition and the contractions become less protracted than they are at present. ACC still exists slightly in the muscles. In this case recovery took place a little over one year from the commencement of treatment.

Another case is that of a girl, seven years of age, whose mother was a trained nurse, and hence the source of information was very reliable. The mother says the child always enjoyed good health till she was six and one-half years of age, at which time she was confined to bed for a few days with catarrhal inflammation of the stomach, and after this affection had passed away the mother noticed slight weakness of the patient's legs. This symptom gradually increased, and at the end of three months she had much difficulty in walking. At present she maintains herself only on her feet by assistance, and frequently crawls on her hands and knees as a method of progression. The child is apparently enjoying good health; there is no impairment of rectal or vesical functions, no existing deformities, and she complains only of inability to use her legs. She cannot maintain the weight of her body on her lower limbs, but with assistance walks with a shuffling gait for a short distance, when she becomes completely exhausted and falls to the floor if not protected. Joint-movements are slow and jerky, the muscles of the legs are soft and flabby, and the plantar reflexes and knee-jerk are totally abolished on both sides. The muscles of the peroneal regions and in the calves of the leg are atrophied to a considerable degree, as a result of which the thigh-muscles have also suffered, as on inspection it is apparent they are not in their normal condition, and there is loss of response when electrically stimulated. Cutaneous sensibility normal; cyanotic condition of the feet. Electrical reactions show that when *faradic* currents are applied to the nerve-trunks above the knee there is but feeble response, even to powerful currents; faradic currents to legs *nil*.

A powerful *galvanic* current applied to the nerve-trunks of the lower limbs gives rise to imperfect contractions. Careful galvanism of the thigh-muscles produces strong contractions—KCC > ACC; the latter is, however, increased. Galvanism of the flexors and extensors of the feet and toes shows diminished electrical reaction; the contractions are slow and tonic in character, and ACC = KCC.

This patient was treated with powerful galvanic and faradic currents, which, when applied at the beginning to the nerve-trunks failed to induce muscular contraction, now demonstrate the return of the muscles to their normal condition. For several months treatment by means of local and central galvanization was persevered in, and there is hope of a good recovery.

Such, then, is a brief history of the few cases of this disease which I have observed, and it is in these cases where electro-diagnosis is of so great importance in helping us to arrive at a definite conclusion and an accurate diagnosis of atrophic spinal paralysis. We should bear in mind that atrophic paralysis is a gradual and progressive disease, which, invading the lower extremities, where its symptoms are most marked, becomes less severe as the disease extends upward. These cases are, in my opinion, illustrative of atrophic paralysis, the course of which may be due, as observed by Erb, to an inflammatory lesion of the anterior horns of the lumbar enlargement, and which diminishes as it ascends into the upper half of the lumbar plexus, the right side being more deeply affected than the left. As regards the electrical reactions in these cases, it was observed that stimulation of the nerve-trunks of the affected parts gave but feeble response to either the galvanic or faradic currents.

Dr. Hughes Bennett has pointed out that in cases of failure of the muscles to respond to the induced current galvanic irritation gives rise to slow and tonic contractions. The occurrence of this disease in children may be partly explained by the inability of the physician to readily recognize the true nature of this disease. In the foregoing cases it is evident that we had to deal with an atrophic paralysis which was gradual and progressive in its onset. There is no doubt that in these cases the galvanic treatment was the chief factor which effected a complete recovery, and that electrical investigation demonstrated the existence of an atrophic condition of the nerves and muscles, and also the presence of reactions of degeneration. Erb speaks of this disease as consisting of a more or less creeping and gradual development of paresis or paralysis, with atrophy and reaction of degeneration, and considers it to be gradual in its ascent, not being limited to single nerves, but involving a whole extremity.

INDICATIONS FOR THE USE OF THE INTRA-UTERINE DOUCHE IN THE PUERPERAL STATE.

By ROBERT A. MURRAY, M.D.,

NEW YORK.

In May, 1887, I was called about forty miles from the city to see, in consultation, a lady living in a malarial region, who had been confined seven days previously with her fourth child.

I learned from her physician that the labor had been normal, with a head presentation, and lasted but two hours; the placenta being expelled, as he believed entire, in about twenty minutes.

Up to the third day everything seemed normal; when, after some nausea and slight pain in the abdomen, a sudden and severe chill in the morning was followed by a temperature of 105°, pulse 120, intense headache, photophobia, and delirium.

Abdominal tenderness and tympanites were soon marked; the lochia became scant and fetid; the secretion of milk was arrested. Believing the attack to be malarial, the physician put the patient on large doses of quinine, with a moderate amount of stimulants, and sought by the use of morphia to quiet the delirium and abdominal pain; but these efforts were ineffectual.

Vomiting of a dark, black watery matter set in on the fourth day, abdominal pain and tympanites increased, headache was intense, the delirium became of a low muttering character, with great prostration; the fever ranged from 103° to 105° each day, and the lochia were scant and very fetid.

Such was the history I received, at the same time being assured that the patient was better, the attack was malarial in its origin, and that he had frequently observed similar cases.

I found the patient in an almost utterly collapsed state; a profuse, cold, clammy sweat covered the body and limbs; face pinched; lips cyanosed; complaint of intense headache and thirst; the pulse, 130 and small; temperature, 104½°; respiration, 40 and panting; abdomen tympanitic; uterus enlarged to umbilicus, very tender to pressure; lochia scant and fetid. I at once expressed the opinion that the patient was suffering from septic endometritis and peritonitis, and that an examination of the genital tract was necessary. This was finally acceded to by the patient, although the physician did not deem it necessary. After a vaginal douche of carbolized water, inspection showed the vulva somewhat swollen, some small lacerations of the introitus, and a laceration of the perineum partially healed but sloughy looking; the vagina was hot to the finger and tumefied; the cervix enlarged, patulous, and badly lacerated; the finger in the uterine cavity detected blood-clots, shreds of placenta, adherent and detached, and a scant, tenacious secretion which, on withdrawing the finger, was found to be ichorous and very foul smelling.

It was advised to use an intra-uterine carbolic injection, to detach with the blunt curette the adherent placenta, and the fetid blood-clots in the mouths of the uterine sinuses, and then to thoroughly wash out the uterus, which would remove the cause of the infection, and prevent its overwhelming the patient. This I did, and, with ergot to keep the uterus contracted, vaginal douches of dilute carbolic acid to render the vagina and cervix aseptic, and a sublimate napkin to the vulva, the patient was left in a clean, comfortable condition. The reaction was slight, and, with the aid of tonics, the convalescence was complete in four weeks, the fever having departed absolutely the day after the douche. The attending physician objected to this treatment, saying that he had always found nature competent to take care of any retained fragments of placenta, and he believed intra-uterine douches an unnecessary interference.

I have not the slightest doubt that without this treatment the patient would have succumbed. I have narrated this case in detail, as its history is similar to that of many cases which I have seen in consultation, and to show the prejudice entertained by some practitioners against antiseptic midwifery, and particularly against the antiseptic intra-uterine douche. It is understood, in the study of the subject of this paper, that this measure is but a part, but still a very important part, of thorough antiseptic midwifery.

No one who knows of, or who has seen, the frightful ravages of puerperal fever in hospital or private practice, will withhold his admiration and respect from those who have worked so earnestly to introduce this method for the benefit of humanity. It is due to them that to-day a patient in a well-conducted maternity has not only as good, but even a better, chance in confinement than she would have ordinarily in her private dwelling.

We shall then inquire:

1. What are the indications for the intra-uterine douche.
2. The method of employment.
3. The contra-indications, and the dangers connected with its use.

As a prophylactic measure, the uterine douche is indicated even in non-instrumental labors—what are frequently called normal labors—when the amniotic sac has ruptured before full dilatation of the cervix, and a prolonged second stage has allowed of contusing and laceration of the parts by the presenting head, and an acrid discharge has constantly bathed the vaginal canal; here, if, as is frequently the case, the uterus relaxes easily, the patulous vaginal canal, unless rendered strictly aseptic, allows readily the introduction of germs, and we are very apt to have subsequent sepsis.

The douche in this case not only cleanses, but, by the stimulant effect of the hot water, promotes efficient and permanent contraction of the uterus, thus closing the mouths of the uterine sinuses, effectually preventing septic absorption. There is no fact more emphasized by statistics in midwifery than this one: That long labors, even where instrumental interference has not been given, or necessary, are frequently followed by fever. The shorter the labor, other things being equal, means safety in the puerperal period.

In complicated labors, where manual or instrumental aid has been rendered, the hand or instruments introduced into the uterine cavity, and the placenta removed manually, more or less bruising and laceration of the vagina, cervix, and endometrium has been caused; in post-partum hemorrhage, not only the result, but often afterward the cause, of uterine relaxation; in placenta prævia, to cleanse the lower zone of the uterus and close the mouths of the sinuses and veins, and prevent sepsis from discharges flowing over the placental site; in rupture of the uterus, complete or incomplete, to wash the débris of clots, shreds of placenta, etc., away, and to disinfect the peritoneal cavity; and, again, in those few cases observed in hospital and poorer private practice, the conditions of atmosphere being favorable to development of sepsis; where the patient has a chill, marked prostration and fever during the confinement, precursing a fever that is ofttimes extremely malignant, a real putrid infection—in all these conditions one intra-uterine douche, given immediately after labor, completes the antisepsis of the entire genital tract, is clearly indicated as a proper prophylactic measure, and in my experience has yielded the most happy results, almost absolutely obviating the occurrence of fever and avoiding any necessity for subsequent interference with the patient. In the treatment of some forms of puerperal fever, we have, in the intra-uterine douche, perhaps our most powerful remedial measure. Puerperal fever presents an almost protean aspect, in its lesions and in its names; to one it is always puerperal peritonitis, to another septicæmia or pyæmia. When we have observed—and with my colleagues in the Maternity I have frequently seen—severe lacerations of the mucous membrane of vagina, cervix, and uterus heal, and extensive exudations in the pelvis absorb, without the slightest fever, thorough antisepsis having been maintained, it is hard to believe otherwise than that all cases of fever depend on septic absorption from without, and are to be treated by removing the source of the infection.

To fulfil this indication the uterine douche should be employed.

Whenever, in the puerperal condition, fetid lochia appear, accompanied by relaxation and uterine tenderness on pressure, with high fever and chill, showing septic endometritis, the uterus should be thoroughly explored with the aseptic finger, and if shreds of placenta, clots, and débris are found, together with adherent placenta, the latter should be detached by the finger or blunt curette, and the cavity of the uterus thoroughly disinfected and cleansed. But I have observed many times pain and tenderness of the womb with high temperature, where the lochia were not offensive and, what to most practitioners is the guide for the intra-uterine douche, namely, fetid lochia, were absent.

There are several causes which may operate to deceive us; the antiseptic we use on the pad or napkin is almost always a deodorizer, or may have a powerful odor of its own which effectually destroys the lochial odor.

The lochia may be very scant, or, what often occurs, may be pent up in the uterus by clots; these facts should be constantly borne in mind.

In all such cases a careful examination should be made of the genital tract, to see that there is no point where sepsis may occur apart from the uterus; if a digital examination shows the cervix enlarged and patulous, the uterus in subinvolution, and the finger when withdrawn has the the necrotic odor of dead tissue, whether there is adherent placenta or not, we should cleanse the uterus immediately. I have never seen a case where, on this being done properly, the temperature has not been reduced, and the injection has seldom had to be repeated. In the treatment of abortion and premature labor the same rules necessarily apply. As here advocated, the necessity for frequent repetition of the douche will seldom arise, but the guide is the septic or antiseptic condition of the uterine cavity; if chill and fever recur and the lochia be fetid, with no other apparent cause, the uterus should be again washed out. The only instruments necessary for the proper administration of an intra-uterine douche are a fountain-syringe with a long rubber tube attached, so that a continuous stream of water may be maintained; an intra-uterine tube of glass perforated with holes, the edges of the latter being smooth, with a terminal opening—Chamberlain's is the one I prefer; a thermometer to indicate the temperature of the water, though the hand will do as a test, if this instrument be not available; and a sheet of thin rubber cloth, such as is used for protecting the mattress.

As portions of placenta and clots may be adherent, in order to thoroughly cleanse the uterus, it is better to have a good Thomas' blunt curette, and a placental forceps—Simpson's I prefer—being made like a bullet-forceps, and narrow at the uterine portion, so that it may be introduced without injuring in the least a cervix slightly larger than to admit a finger.

Having a proper supply of hot water ready, of a temperature of 110° F., the patient is moved and placed in the lithotomy position on the edge of the bed, the rubber cloth is pinned around the waist, extended under the hips, and gathered below so as to form a funnel conducting the water to a receptacle on the floor.

The patient is covered with a blanket to keep the limbs warm, and the tube, with the water constantly flowing so as to exclude air, guided by two fingers, introduced, the vagina washed out; then it is passed, following the curve of the pelvis, into the uterus; the external end, being gradually depressed, causes the internal end to follow the curve of the uterine cavity, the two fingers forming a groove in which the tube lies, and allows of the free exit of the water. One of the assistants, holding the thigh, grasps the uterus firmly with his free hand and keeps it contracted, but does not press the uterus, as a whole, downward into the pelvis—a procedure which often bends the body on the neck and occludes the canal, also causing contusion of the cervical mucous membrane.

The flow is continued until the discharge is perfectly clear and inoffensive, when the tube is withdrawn with the same care as in its introduction, the water still flowing, to free the vagina of débris which may have lodged there.

An antiseptic napkin is applied immediately to the vulva, the rubber unpinned, the patient is washed, the bandage applied, and she is now restored to her ordinary position.

The composition of the injection is usually carbolic acid 2 to 100, or corrosive sublimate 1 to 3 or 4,000. Liquor sodæ chloriatæ, permanganate of potassa, and other disinfectants may be used, but I believe carbolic acid and sublimate to be the best.

Our next inquiry is as to the dangers supposed to attend the use of, and the objections to, the intra-uterine douche.

The first objection urged is that the proper administration of the injection requires movement of the patient, and there is danger of hemorrhage—dislodging of clots, causing embolism. Again, the introduction of the finger and tube into the uterine cavity may bruise the endometrium, abrade some granulating wounds in uterus or vagina, and open new points for infection; or possibly infective material may be carried from the vagina and outside into the uterus. After intra-uterine injections collapse has been witnessed from over-distention of the uterus. Passage of fluid into the peritoneal cavity by the tubes, and entrance of air into the veins, has caused sudden death. Poisoning has occurred by the absorption of the disinfectant employed.

In answer to these objections, I would direct attention to the fact that, as described, the patient is not lifted at all, but merely moved around, while on the bed, to its edge; nor need the head be raised, which might lead to syncope. No infective material can be carried into the uterus, if the flow of water douche the vagina thoroughly, as described, before the fingers and tube are introduced into the uterus.

The endometrium will not be abraded if the curve of the uterus and pelvis be followed, and the raw surfaces left by the use of the curette are immediately disinfected and constringed by the hot water and acid, and, if sublimate be used, are coated with a layer of albuminate. Shock, collapse, and peritonitis may be avoided by the firm grasping of the uterus by the assistant, and by the retention of the finger at the cervix to keep the outflow free.

The cases of collapse and peritonitis reported have mostly, if not altogether, occurred when iron or other styptics have been employed, in a relaxed condition of the uterus, to control hemorrhage; sudden contraction of the uterus was produced; the exit of the injection being arrested by firm clots in the cervix, the fluid was expelled through the tubes into the peritoneal cavity.

For the reasons given before, the flow of the syringe being continuous, and the canal of the vagina being full of water, air cannot enter the uterus. Carbolic or other poisoning cannot take place if firm contraction of the uterus is maintained at the time by the hand and the hot water, and subsequently by ergot, as the fluid is thoroughly expelled and the mouths of the placental veins and sinuses are closed.

Iodoform, according to Spaeth's formula, I have employed in conjunction with the douche occasionally, but only to heal the lacerations of the mucous membrane, as I, similarly, dust the powder over the external genitals, when lacerated; but I believe the powerful odor of the iodoform conceals the offensiveness of the lochia, and tends to a feeling of security which is sometimes prejudicial.

Many cases of iodoform-poisoning have been reported, so that its use is not unattended with danger, and lately experiments have seriously called in question its germicidal powers.

It is not my intention to convey by this paper the idea that it is advisable or necessary to employ antiseptic intra-uterine douches in each midwifery case. Only a limited number require them; but in the class of cases described their use, I believe, is advantageous, and ofttimes imperative, if we would save our patients, and, what is also to be thought of, diminish the number of puerperal fever cases, each one of which may be the source of contagion for others.

Finally, the physician himself should always administer the injection; he alone understands what is sought to be attained and the possible dangers—it never should be left to the nurse, however experienced.

235 West Twenty-third Street.

Acid Bichloride Solutions in Antisepsis.—Dr. Ernest Laplace, of New Orleans, has, since last March, been working in Berlin under the direction of Dr. Koch. He has been engaged chiefly in bacteriological investigations, and one result of his labors will, no doubt, have great influence upon the future of surgical dressings. Bichloride of mercury, demonstrated by Koch in 1881 to be the best of antiseptics, did not do all the work that had been anticipated for it in surgery. It was found that, as soon as a sublimate solution came in contact with an albuminous fluid, the albumen coagulated and formed, with the bichloride, a precipitate which had lost all disinfectant properties. Dr. Laplace proved, by a series of experiments, that not only is the precipitate devoid of disinfecting power, but also the supernatant liquid. In order to retain in dressings all the virtues of the sublimate, Dr. Laplace perceived that it would be absolutely necessary to prevent the formation of such a precipitate. After many fruitless experiments he found at last the principle of the action which he was seeking, namely, the addition of an acid to the solution of corrosive sublimate; such an acidulated solution will not form an insoluble albuminous precipitate. Dr. Laplace usually added five parts of hydrochloric acid or tartaric acid to a thousand parts of a solution of corrosive sublimate (1 to 1,000), though occasionally he substituted tartaric or carbolic acid. Of this acid solution Dr. Laplace says that: 1, It makes no deposit of sublimate after standing (as all the sublimate solutions do), thereby retaining a permanent strength; 2, when brought in contact with an albuminous fluid, the albumens will remain in solution, and the whole strength of the solution of sublimate will be obtained as in non-albuminous fluids; 3, an acid medium is unfavorable to the development of micro-organisms. The addition of an acid to a sublimate solution also increases its disinfecting powers, so that a much weaker solution is required.—*N. O. Med. and Surg. Journ.*

Clinical Department.

ALCOHOLIC ATAXIA.[1]

By JOHN M. CLARKE, M.D.,

BURLINGTON, VT.

THE case is that of a man, aged thirty-one, single, by occupation a woollen manufacturer. His work was the supervision of the weaving department, having twenty-five or thirty men under his charge, making his position one of great responsibility to the concern. He is a man of good intelligence and fair education. For the year previous to my knowing him he had not attended to any business. His family history had nothing to influence the case; general health usually good; not given to excessive venery. I made careful inquiry as to his occupation and manner of life, and could find nothing to bear upon his condition except alcoholism. He had drunk alcohol for five or six years, at times to excess; and during the past two years had taken it, mostly whiskey, to great excess. For weeks at a time he drank day and night, often going without food for two days at a time. Had had delirium tremens twice, the last attack about three weeks before coming here. The history showed that his alcohol-habit was certainly sufficient to produce any form of trouble that may arise from its use. I understand he showed considerable difficulty in walking several weeks before coming here, but it was thought to be a stagger and tremor, and no particular attention was paid to it.

He finally became so bad in his habits and unmanageable in manner that it was necessary to send him from home, where his appetite could be restrained and such treatment pursued as he needed. When admitted he was quite wild, bordering upon mania. He had a quantity of whiskey with him, and had been allowed to drink on the route; consequently he was full. He had what I thought was an ataxic gait, but the circumstances were such that I paid but little attention to it at the time. During the following week he went through the usual form of "cleaning up," only that his stomach was more irritable than is usual in cases of alcoholism, and this was complicated with a profuse diarrhœa, which added severity to the condition. He became excited, incoherent, and noisy. During the first month there was no improvement, but a failure of strength, until it became an anxious question whether he would live to demonstrate his real condition. However, under a tonic form of treatment he came rapidly up again. Appetite became good, and he regained his normal condition to a good degree.

I have passed rapidly over this time, only wishing to bring out such points as will give you an idea of what he passed through while producing the ataxia. As soon as practicable several very careful and thorough examinations were made, and I became convinced that I had a case of locomotor ataxia. Every test used I tried. His gait was very characteristic, patella-reflex gone; he could not stand with his eyes shut, or walk without looking at his feet. He was also ataxic in the upper extremities. He could not rapidly touch his nose or any specified part of the face; could not put drink to his lips without spilling it. He had lancinating pains in spots in his legs and feet. These were so severe that he would scream out at the pain. If it was necessary to touch his limbs, it was done in the most careful manner. In short, I thought it a well-marked case of locomotor ataxia, and I informed the family of my conclusions. My prognosis was of course unfavorable to recovery. Mentally he was excited, at times wandering in thought—called upon old associates, and lived over old scenes. The treatment was variable, but electricity, both galvanism and faradism, was persistently used, together with rubbings. Iron, strychnine, and tonic, with nourishing diet, and such other medication as was indicated, were prescribed. In about six to eight weeks from the commencement of the active treatment he began to improve. First he could stand better, next he could walk alone, then he fed himself, and so the change went on. Friends came to visit him. I explained to them that he was much improved, but I thought only temporarily, still adhering to my original diagnosis. He was so much better that he was removed home to a distant State, to be near the family and friends. The treatment I was pursuing was to be continued by the physician there.

I have been in constant correspondence with the family, and he is now, after two years' duration, considered well. I have a letter from him in his own handwriting, dated September 21, 1886, which says he is perfectly well, except a weakness in the hands.

The recovery of this case has satisfied me of my error, and that it was alcoholic ataxia instead of locomotor ataxia.

It is very difficult to decide between two diseases with the same symptoms in each, and it is well to be a little slow in committing one's self to so important a decision. In looking up this subject, I find the literature is not plenty.

J. Dreschfeld published his observations on alcoholic paralysis in 1884, which excited general interest and brought out able articles, with report of cases, in Europe and America. In a subsequent article he refers to these.

He now divides alcoholic paralysis into two groups—alcoholic ataxia and alcoholic paralysis, the more prominent symptoms naming the class. He very properly claims that it is necessary to distinguish between cases where there is marked inco-ordination without much paralysis and those where paralysis is most marked, and considers the ataxic form the milder type of the disease. In the ataxia, patients complain mostly of pain in the legs and feet. He gives the usual ataxic symptoms—ataxic gait, ataxia of the hands, inability to stand with closed eyes, and loss of patella-reflexes. All these symptoms I have noted as well marked in this case. The mental symptoms in this case, perhaps, are characteristic of this condition. His favorite illusions and delusions were holding repeated conversation with former friends and acquaintances, giving orders about his wants to old companions, directing about his business as if in active occupation. Another frequent idea was travelling to and from familiar places. He would reply to questions correctly, at the same time calling the person addressing him by the name of some old friend.

The pathological change which causes locomotor ataxia is central—that is, in the posterior columns of the cord—and is permanent. In alcoholic ataxia the change is peripheral, and is transient, as a rule, with treatment. The recovery in this case demonstrates this fact.

Ross, in his admirable work on nervous diseases, has a short article on alcoholic paralysis, giving similar symptoms in the ataxic form which I have noted, and says recovery is the rule.

Buzzard, of London, published a little book in 1886, on "Paralysis from Peripheral Neuritis from Gouty, Diphtheric, and Alcoholic Origin." After citing several cases of paralysis from these causes, which were peripheral, and recovered, he concludes the cause to be neuritis.

It is pretty satisfactorily settled that alcoholic paralysis, as also paralysis from diphtheria, gout, and lead, is peripheral in origin, and caused by multiple neuritis. Neuritis is usually due to exposure, or to some toxic element taken into the system. Among these are alcohol, diphtheria, arsenic, rheumatism, lead, and syphilis.

An editorial article in THE MEDICAL RECORD of September 25, 1887, brings out some points which were prominent in the case I presented, particularly as to the ataxic form, in which the symptoms resemble locomotor ataxia—marked ataxia without any great loss of muscular power, tendon-reflex gone, etc. These may deceive the physician and lead to a wrong diagnosis and prognosis.

The experience of the case which I have related has taught me, 1, that great care should be exercised in making a diagnosis from symptoms of ataxia, and that the prognosis should be guarded; 2, that the origin of alcoholic paralysis and ataxia is peripheral, and caused by neuritis; and, 3, that alcoholic or peripheral paralysis is curable under favorable circumstances and with proper treatment.

[1] Abstract of a paper read before the Vermont State Medical Society.

COMPLETE PROCIDENTIA—ALEXANDER'S OPERATION—CURE.

By WILLIAM H. NAMMACK, M.D.,
NEW YORK.

Ella J——, aged twenty-nine, married six years, III.-para, has never had a miscarriage, and was delivered of her last child two years ago, since which time she dates her illness. The patient came under my care in June, 1887, and gave the following history: For the past two years she has had profuse menorrhagia, occurring at intervals of three weeks and continuing for from seven to ten days, constant pains in the back and loins, great difficulty and pain in locomotion and defecation, severe vesical irritation, profuse leucorrhœa, and has progressively lost strength, so that at present she is scarcely able to stand erect. She is very much emaciated and has become a confirmed invalid, stating that she has not enjoyed a single hour's freedom from pain, and believing, in view of the many failures to obtain relief, that she is destined to a life of perpetual suffering. She has been kept in bed for weeks at a time, has been tamponned and douched assiduously, has worn pessaries of various descriptions until she is unable now, even after careful preparatory treatment, to retain an instrument for the shortest space of time, and has had her perineum repaired, having been persuaded that an operation was her only hope. But her symptoms have grown steadily worse, and she is now thoroughly discouraged. Examination reveals complete procidentia, rectocele and vesicocele, rupture of perineum down to sphincter ani, and extensive bilateral laceration and hypertrophy of the cervix. The left ovary is found to be enlarged, distinctly prolapsed, and very tender. The uterine sound shows retroversion, but without adhesions, as the displacement of the organ can be readily reduced.

In view of these facts, it was determined to attempt a permanent return of the uterus to the pelvic cavity by the following means: To shorten the cervix by amputation, to repair the perineum, and to lift the organ upward and forward in the pelvic cavity by shortening the round ligaments. On July 30th the cervix was amputated to the extent of half an inch, the cut edges being united with silver sutures, and a stem of hard rubber being introduced into the os to prevent complete closure. The perineum was repaired by Emmet's method, and a tampon placed in the vagina to retain the rubber stem in the os of the cervix. The tampon was removed next. One week later the sutures were removed from the cervix and perineum, and union was found to be perfect. The uterus was still down on the perineum, retroverted but freely movable. The left ovary was prolapsed, enlarged, and sensitive. On the tenth day after the removal of the sutures from the cervix and the perineum, the round ligaments were shortened and attached to the pubic spines with silk-worm gut. The external wounds were united with continuous sutures of coarse silk and dressed antiseptically, and a flexible rubber ring was introduced into the vagina to support the uterus and to relieve the ligaments of tension. The external sutures were removed on the third day and the wounds united by first intention. This was my third case of Alexander's operation, and from the first of these, as well as from some others which I had an opportunity of seeing, I had learned that, if suppuration took place in the external wounds, it was often followed by separation of the round ligaments from the pubic spines and consequent failure of the operation.

The patient continued to improve, and the flexible ring gave her so little inconvenience that she was unaware of its presence until it was removed by me in order to cleanse it. She was out of bed in twelve days, and was advised to continue wearing the rubber ring for a few weeks longer. Five weeks from the day on which she came under my care she was in splendid condition, and had had no pain, no discharge, no vesical trouble (with the exception of slight incontinence of urine on the day following the shortening of the round ligaments, probably due to pressure from the anteverted uterus), and, as she expressed it, "was able to dance a jig." Examination now showed that the uterus was in normal position, and that the left ovary was of normal size, not at all tender, and restored to its proper place. This was in August, 1887, and now, nearly seven months later, the patient states that she has never had one bad symptom since, while examination reveals no sign of any return of the trouble. In fact, she is practically cured.

This case seemed of some interest, because of the previous futile efforts to retain the uterus in the pelvic cavity by the usual means, and because it illustrates conditions under which, in the face of the complete failure of all other measures, the operation of Alexander can effectually procure a thoroughly and permanently successful result.

Progress of Medical Science.

The Imbibition of Poisons.—Professor Reese discusses the question of the post-mortem imbibition of poisons and the means by which such a condition may be distinguished from ante-mortem poisoning. The vital point in determining this matter, in Professor Reese's opinion, is to settle whether the poison can reach the brain and spinal cord by imbibition. The evidence is not as yet conclusive in regard to it, and he points out the necessity for care in making experiments on this point, for, if any fluid were allowed to regurgitate from the pharynx into the posterior nares, it might reach the brain readily through the ethmoid cells, but it has yet to be proved that it can reach it by imbibition from the stomach. Another point on which decisive information is wanting is whether poison can get into the urine by imbibition; it is well known that the walls of the bladder may be invaded by the poison in this manner, but it is not certain whether the poison has actually found its way into the urine under such circumstances. If it cannot, then we should have a reliable test of ante-mortem poisoning in the presence of poison in the urine, though the absence of poison in the urine would be no proof that the case was not one of poisoning during life. The discovery of poison on the surface of organs and not in the interior would, if clearly made out, be strongly presumptive of post-mortem imbibition.—*The Medico-Legal Journal.*

Syphilitic Ulcerations of the Female Urethra.—Dr. Landau has described the different forms of ulceration of the urethra in women and their causes—mechanical injury, parturition, diphtheria, bacterial infection, gonorrhœa, chancre, tubercle. He also records five cases of what he calls "ulcus rodens urethræ." This consists of a process of ulceration which slowly and continuously destroys the walls of the urethra, but not the adjacent tissues. It gradually extends from the urethral orifice toward the bladder, and only ceases when the whole extent has been involved. There is no tendency to new formation, nor to healing. For a long time it gives rise to so little inconvenience that the patient is quite unaware that there is anything wrong until the occurrence of marked suppuration or of incontinence of urine attracts her attention. On examination, the meatus urethræ is found covered with pus and studded with a number of uneven swellings, between which are deep fissures. These swellings resemble pointed condylomata, are soft to the feel, bleed very readily when touched, and often fill the urethra as far as the neck of the bladder. If the finger is introduced a rough surface is felt, and the canal is found to have become narrower toward the bladder, so that it seems to be conical in form, the apex of the cone being toward the bladder. From the vagina the urethra and periurethral tissue feel thickened and infiltrated. Four of Dr. Landau's patients were undoubtedly syphilitic, and the fifth also had probably suffered from syphilis. The author considers the ulceration to be syphilitic in character; but he only looks upon syphilis as the foundation on which the ulcerative process —the exact nature of which is unknown—develops itself. The prognosis, as regards life, is not unfavorable, unless the process extend to the bladder and the kidneys become implicated. But a perfect cure is never to be looked for, and complete cessation of the destructive process is very rare. Scraping, followed by the application of lactic acid, is the treatment recommended by the author. Antisyphilitic remedies proved useless in his hands, but he thinks they might be of service at an earlier period.—*Archiv für Gynakologie.*

The Modern Climatic Treatment of Phthisis.—Dr. J. A. Lindsay has published an instructive paper on "Climate as a Therapeutic Agent in Phthisis" (*The Lancet*). He is decidedly of opinion that phthisis is a curable malady. To the question, "How does climate cure phthisis?" he answers, "by removing the consumptive from the evil influences of unfavorable meteorological conditions and of an injurious soil, and by transferring him to a climate where fresh air, sunshine, and an out-door life may be freely enjoyed, and where, in consequence, the processes of respiration, digestion, and sanguification proceed with sufficient energy to combat successfully the hereditary tendency or individual proclivity to pulmonary disease." After giving an account of those climates which are most likely to cure phthisis, the author concludes as follows: "Hippo, paregoric, and squills have almost disappeared from our treatment of phthisis; and climatic sanatoria, which soothe the patient's cough at the expense of his appetite and strength, must follow them into deserved oblivion. The consumptive does not die of his cough. He dies of progressive wasting. We have thrown aside expectorants and anodynes in favor of good food, exercise, and such aids to nutrition as cod-liver oil, hypophosphites, maltine, etc., and we must, when possible, choose climatic resorts which are tonic and stimulant rather than those that are mainly sedative. The vital point about any climate is, will it promote nutrition? In early uncomplicated cases with vigorous circulation the mountain climates offer the best hope. If the circulation be feeble, or if there be much nervous irritation, the choice will lie between the sea-voyage and residence in such dry inland resorts as Upper Egypt or the interior plains of Australia. The sea-voyage has the great recommendation that it rarely does harm, except in those very advanced cases which are beyond the reach of all treatment. If the patient objects to the mountains and shrinks from the long sea-voyage, Algeria or Morocco should be preferred to France or Italy. Climatic change is a snare instead of a help, a curse rather than a blessing, if it be regarded as a complete therapeusis in itself, and as enabling the patient to dispense with the usual lines of treatment and his customary precautions. Climate is not a specific. At best it is only a condition of cure, and we may expect it to be effectual only when the patient's food, habits, occupation, and mode of life are wisely regulated so as to facilitate its beneficent influence."

Primary Mycotic Nephritis in Children.—According to Dr. S. Miscoli (*The London Medical Record*), during one month of the autumn of 1887, in a town of three thousand inhabitants, fourteen cases of primary nephritis occurred in children from three to ten years of age. No epidemic prevailed at the time, and there was no rheumatic cause of any kind. The illness began with high fever, lasting three or four days, and giving place to œdematous collections of peculiarly hard character. Death ensued, or else convalescence, within a fortnight; there were three deaths in all. Microscopical examinations were made in the laboratory of Professor Guido Tizzoni, of Bologna, during the past month. 1. Sections of the kidneys of a boy, three years of age, who died on the fifth day of illness, showed, when treated by Gram's method and after-stained with carmine, numerous violet spots in the cortical periphery, the glomeruli, toward the middle of the pericanalicular vessels, and, lastly, in the tubules. Highly magnified, these spots showed longish ovals, some being even rod-shaped, surrounded by a whitish capsule, and always in pairs. Sometimes they were in series or chains of four or six together, more often grouped to form the violet spots. The thrombi, which either merely filled up or else dilated the vessels of the cortex and pyramids, were made up of these spots. At present no hypothesis is ventured as to these elements, but the author considers them to be certainly very like pneumonococci, as Klebs has delineated them in "Pathological Anatomy," and as he found them in the kidneys of a patient who had died of pneumonia. No micro-organisms were found in the kidneys of the two other children, who died on the sixth and tenth day of illness respectively, but only signs of general inflammation. 2. Sections of the first case, treated with logwood and carmine, showed the epithelium of the tubules in a state of cloudy swelling; the cell-nuclei were almost entirely lost to view, and only their peripheries were visible (nuclear membrane). But the cells contained numerous well-stained small bodies, which gave the impression of micro-organisms. The chromatin had escaped from the nuclei, and resembled Flemming's colored granules in the cell (the cell-membrane showed mulberry-like projections), as Madame Dr. Cattani has observed in rabbits after artificial pneumonia from pneumo-thorax, but the process has not yet been seen in the kidneys. The inflammation was not glomerular or glomerulo-capsular, but rather a general mycotic inflammation of the whole kidney. Primary nephritis is always rare in children, and has not yet been described as an epidemic.

Penetrating Gunshot Wounds of the Chest.—Dr. Gouzier has published some observations and statistics regarding the penetrating gunshot wounds of the chest occurring in the French expeditions to Formosa and Tonquin in 1883–85. From his work we gather that such wounds showed a mortality of ten per cent., which is only about a sixth of that due to similar wounds in recent European wars and in the American war. Apparently, as he suggests, the general employment of antiseptic methods was the cause of this great amelioration. Chest-wounds from revolver-balls of seven millimetres in diameter generally proved comparatively harmless. Traumatic pleurisy and pneumonia usually terminated favorably, but hemorrhage, empyema, and compound fracture of the ribs gave much more serious results. He found that the best practice was not to explore unless it was necessary to extract the ball, and not to attempt extraction unless the ball was just beneath the skin or was setting up dangerous complications. In ordinary cases he found the best plan was to close the wound antiseptically; but if there were empyema, to make a counter-opening and to wash out and drain the pleural cavity. Warm antiseptic baths were also found very useful in Tonquin.—*Lancet*, January 7, 1888.

Pleasant for Lady Medical Students.—The increase of female medical students at the École de Médecine in Paris does not excite pleasure among their male colleagues. We learn from a correspondent of *Daniel's Texas Medical Journal* that "it is only necessary to make a start for a manifestation, and everybody joins in, lecture or no lecture. Especially when a young lady comes in a little tardy, a demonstration is almost inevitable. A drawling 'o-h,' passing through every note for a nine-scale piano comes from several hundred strong vocal apparatuses, and as the grand closing finale a general smacking of the lips, kissing, and other indefinable sounds make themselves heard from every corner."

THE MEDICAL RECORD:

New York, March 17, 1888.

THE PATHOLOGY AND CLINICAL TYPES OF TYPHLITIS.

In a paper read by Dr. J. H. Musser, before the Philadelphia County Medical Association, recently, some interesting points were brought up regarding the difficult subject of the pathology and diagnosis of pericæcal inflammations. Dr. Musser introduces, first of all, more specific terms for the various forms of inflammation occurring in and about the cæcum and appendix. Thus he says: "By typhlitis is understood inflammation of the cæcum; by perityphlitis, inflammation of the peritoneum covering the cæcum; by paratyphlitis, inflammation of the connective tissue behind the cæcum. The term appendicitis is used for inflammation of the appendix; appendicular peritonitis for typhlitis of the appendix and its serous covering, and paratyphlitic, or pericæcal inflammation, for inflammation of the connective tissue around the appendix."

The term typhlitis may be also used as a general one to cover all the forms of inflammation occurring in the right iliac fossa.

Next, as to the anatomy of the parts, Dr. Musser gives the results of the studies of Treves and Fitz on this subject. Treves thinks that the cæcum is most frequently found, not in the right iliac fossa, but on the psoas muscle itself, or in the pelvis; that the cæcum is entirely surrounded by peritoneum rather than only partially, and therefore that behind there is no areolar tissue, as was described by the older anatomists. He does not believe, moreover, that there is a mesocæcum.

The usual position of the appendix is behind the ileum and its mesentery, with the tip pointing toward the spleen. The second most usual position is behind the cæcum, with the tip pointing upward. Long appendices usually take this upward direction.

The appendix may also stretch across the pelvis and become adherent to the sigmoid flexure. It varies in size, being from one and a quarter to nine inches in length.

Regarding the pathology of the appendix, it may be the subject of simple catarrhal or ulcerative inflammation. In the latter case there is local peritonitis, perforation, and formation of abscess. The location of the abscess, for it is usually circumscribed, depends upon the position of the cæcum. There are three positions in which it is most frequently found—in the right iliac fossa just above Poupart's ligament, or behind the cæcum, or in the pelvis. The size of the abscess varies, sometimes containing only two or three ounces of pus, and in other instances as much as a pint or more has been removed. The walls of the abscess differ according to its position.

The perforation always occurs within one and a half or two inches of the colon.

The important point made by Dr. Musser, if we understand him correctly, is that most cases (ninety per cent.) of typhlitis, using the word in its general sense, are cases primarily of perforative appendicitis, due generally (sixty per cent.) to the presence of a foreign body occluding the canal.

In the discussion of the paper above briefly outlined, Dr. William Pepper stated that he believed there were two classes of cases coming under the head of typhlitis. In one, the affection is limited to the cæcum and pericæcal connective tissue, while the appendix is very little affected. These cases are comparatively frequent, and they generally end in resolution.

In regard to symptoms, more cases are characterized in the beginning by pain, not excruciating in character, not associated with evidence of collapse, often accompanied with nausea and vomiting, and with elevation of temperature, which continues to rise until decided fever is present. With these symptoms there is excruciating tenderness in the right iliac fossa, a sense of fulness and induration, not rarely with dorsal decubitus and flexed thigh, with a constipated condition of the bowels, possibly preceded by one or two irritative movements during the first day, and with these there is considerable acceleration of the pulse. In proportion as the induration and swelling is early and marked, the chances are that the appendix is not seriously involved, but that the affection is chiefly one of inflammation of the walls of the cæcum and of the pericæcal connective tissue, with exudation, usually accompanied with considerable fecal impaction of the cæcum.

The treatment consists of abstinence from food and absolute avoidance of interference with the state of the bowels, local depletion, counter-irritation followed by the application of the ice-bag, or warm fomentations and the early internal use of opium and mercury.

The second class of cases includes those of appendicitis with perforation. The first symptom here is usually intense and excruciating pain, so severe at times as to cause collapse, occasionally so severe as to be followed by death in a few hours. Following this there is the rapid development of the signs of peritonitis. The pulse becomes frequent. There is marked tenderness, not in the iliac region only, but also toward the middle of the abdomen. The belly becomes distended, but there is no induration to be felt; there may even be no fulness in the right ileo-cæcal region. The appendix often lies under the cæcum, and there may be no evidence of dulness or of induration.

The fever may be moderate for a few days, with only slight pain. There is less vomiting than in the other form, and the patient may, for a short time, seem to be improving. The bowels are quiet and not so obstinately constipated as in the other form. After a time symptoms of general peritonitis appear, and unless there has been surgical interference the patient dies in from five to ten days.

As so much depends upon proper surgical measures, Dr. Pepper rightly dwells upon the importance of distinguishing these two forms from each other. It seems, however, as yet impossible to lay down any absolute rules of diagnosis. Rectal examination and the use of the aspirator needle are often very important and helpful measures.

A LAW DISPENSARY.

THERE has been established in this city a bureau to which poor people can resort for legal advice free of charge. This bureau was opened under the auspices of reputable lawyers in connection with Rev. Mr. Goss' People's Mission.

There is an opportunity for much good to be done by such a dispensary, and we congratulate the legal fraternity on having joined hands with the medical profession in the organization of philanthropic work.

Law and benevolence are not ordinarily thought to go hand in hand; but no doubt, with the aid of some pastoral appliances, they can be jerked along together for a bit.

We only hope, out of brotherly feeling, that law dispensaries will never grow into such an incubus as medical dispensaries have done, that they will never be used for advertising purposes, or for working up a private business, or for exploiting the good works of the business managers. The medical profession can tell the legal profession a great deal about the lights and shadows of the dispensary system.

THE PROBLEM OF DISSOLVING URIC-ACID CALCULI.

EVER since urinary calculi were first recognized, the attempt has been made to find some means of dissolving them in the body. The operation of lithotomy, though not particularly hazardous under favorable conditions, too often hastens death to be attempted when milder means will cure. The brilliant experiments in the laboratory as to the solubility of calculi at first led physicians to believe that their removal was a very simple matter, but, unfortunately, clinical experience in no way justified this inference, and, as time went on, the prevention and dietetic treatments were the only ones in use.

Dr. C. Posner and Dr. H. Goldenberg (*Zeitschrift f. klin. Med.*, 1888, xiii., H. 6.), however, not willing to be discouraged at the hitherto unsuccessful task, have endeavored to study this subject anew, hopeless as it may seem, and in the first series of experiments they confine their attention to the most important constituent of all calculi, viz., uric acid, and to a study of the different alkalies which are well-known solvents of these calculi.

At the instigation of Ebstein, Jahns (*Archiv d. Pharmacie*, vii., 1883), in Göttingen, studied this subject, but he made the mistake of forgetting that substances, however capable of dissolving uric-acid calculi outside of the body, underwent great changes in their passage through the body and often lost their effect. As an example of this is given the carbonate of lithium, which ordinarily forms with uric acid the most soluble compound, while, when taken internally, it appears in the urine, in combination with chlorine, as the chloride of lithium, a most insoluble substance.

Emil Pfeiffer and F. Bergmann ("Verhand. d. V. Congr. f. in. Med.," Wiesbaden, 1886, S. 444) came nearer to the clinical aspect of the question when, instead of using the mineral waters themselves, they took the urine passed after the use of the mineral waters, at the same time taking into consideration the individual peculiarities of the individuals themselves. Posner and Goldenberg followed the method of Pfeiffer, by taking two hundred cubic centimetres of filtered urine from individuals to whom had previously been given one of the drugs or mineral waters supposed to dissolve the calculi. This urine was passed through a filter containing a known quantity of chemically pure uric acid. At the beginning of these experiments they took two hundred cubic centimetres of "normal urine," that is, urine from one individual to whom none of these drugs nor mineral waters had been given. These two hundred cubic centimetres of normal urine were passed through a filter containing a known quantity of chemically pure uric acid, and, after the uric acid had been weighed, it was found not only not to have lost by the filtering action of the urine but even to have slightly increased in weight, the normal urine exerting no solvent action on the uric acid.

After experimenting with a number of alkaline mineral waters, among which were Vals and Vichy (Grand Grille), and also with such drugs as the bicarbonate of soda; Cantani's alkaline powder, consisting of bicarbonate of soda; effervescing carbonate of lithium and citrate of potash, the carbonate of lithium, borax, the boro-citrate of magnesia, and a remedy called "litholydium," they found that these remedies, although not having exactly the same effect on the urine, made it less acid or even alkaline, increased its amount, and, *pari passu*, decreased its specific gravity. The conclusion seems to be, that the bicarbonate of soda deserves the lion's share of the success, and the two most beneficial mineral waters, Vals and Vichy, are richest in sodium. The other effects of this treatment, namely, the increase in amount and decrease in specific gravity, are not to be left unconsidered. The solvent power of the urine increases with its lessening specific gravity, and the large quantity washes out and dissolves the small gravel. Experience showed that such waters as Vals or Vichy were more powerful than twice the quantity of a water one-half as effective; *i.e.*, that the concentration was important. Also, the mineral waters were much better than the salts contained in them and taken in the same doses, for the effect was most marked when the urine was slightly acid or neutral, intense alkalinity of the urine causing a precipitation of the almost insoluble salts and earths; the mineral water containing free as well as combined carbonic acid, a slightly acid or neutral reaction was easily maintained.

Now, what can be deduced from the above experiments for the benefit of our patients? There are cases of the uric-acid diathesis where deposits may be formed in the kidneys, leading to attacks of gout. If it is a question of an acute attack, then the most powerful means should be used, as Vichy and Vals water. Unfortunately, the waters of these springs are not always accessible, and often expensive, and so a resort to the bicarbonate of soda, in doses of from fifteen to seventy-five grains a day, taken in divided doses in large quantities of effervescing water, is often advisable. The next best thing is Cantani's effervescing powder or the carbonate of lithium. In the more chronic conditions, and in the interval of an attack, the weaker mineral waters, or such drugs as the boro-citrate of magnesia or borax, are to be recommended. Too long use of Cantani's powder is not to be advised, on account of the lithium and potash contained in it.

In the whole treatment it is necessary to control the reaction of the urine as far as possible, and not let it get too alkaline. The difficult thing is to completely dissolve large calculi. Such a thing is possible, but almost more difficult in proportion to the surface exposed to the volume of the stones. Ebstein seemed to think that the effect was principally due to the flushing action of the increased quantity of urine; but Posner and Goldenberg are convinced that the mineral water or drug in medium doses is borne well and exerts a favorable solvent action on these calculi. These experiments are certainly very valuable, and the treatment is one to which all patients will willingly submit. The dangers of using mineral waters in excess has of late been pointed out, and these should be considered in the treatment.

THE PHYSICAL PROGRESS OF WOMAN.

One of the most striking signs of the advancement and emancipation of woman may be noted by the student who philosophically observes the posters of Barnum's circus. The number and variety of wonderful feats performed do not increase, but they are gradually being done more and more by women. We see in the future a time when the only share of ignoble man in and about the arena will be feeding the elephants and driving the horses. It was but a short time ago that a lady lion-tamer nearly had her head bitten off, being the first woman who has ever had a professional experience of this kind. Mr. Barnum announces "the only lady knife-thrower," to say nothing of lady snake-tamers, a lady who walks on the ceiling, a troupe of lady "trapezists," a lady wolf-tamer, a lady who is shot out of a cannon, and a lady who "warns, comforts, and commands" some twenty odd elephants.

BACTERIOLOGICAL WATER-TESTS.

At a recent meeting of the Society of Medical Officers of Health, a report of which appears in *The Lancet* of January 7, 1888, the value of testing the fitness of water for drinking purposes by means of bacterioscopy was discussed. Our readers, doubtless, remember the valuable researches of Prudden on the bacteria of ice, which were published in The Medical Record. The results obtained by this author are not altogether paralleled by the conclusions of Mr. Bischof, who read the paper of the evening at the meeting referred to.

Among other things Mr. Bischof investigated the influence of an extension of the time of culture in Koch's bacteriological water-test. He found a large increase of colonies of bacteria by extending the time ordinarily allowed for their development. This extension of time is produced, according to the author, by spreading a minute quantity of potassic permanganate or spongy metallic iron upon those colonies which encroach unduly upon the development of the others. In this way certain colonies are sterilized, while others are given a chance to develop. Samples of potable water to be tested should, for obvious reasons, be taken as much as possible subject to the conditions under which the water is consumed.

The conclusions formulated by Bischof, as the result of his studies, are as follows: 1. No bacteriological water-test can satisfy the demands of hygiene unless it is qualitative, distinguishing between harmless and pathogenic microphytes. No such test is at present known. 2. Merely numerical results without such distinction are entirely unintelligible, unless the time and other conditions of culture of each test be specified. 3. A small portion only of the colonies capable of growing in gelatine-peptone is indicated by three days' culture. 4. The ratio of colonies thus indicated by three days' culture to that of the total present appears to differ so widely in different samples that the numbers of colonies obtained from them cannot be compared with each other. 5. Instead of any such comparison, the changes taking place from time to time should be followed up in each sample separately. 6. Extension of culture beyond three days increases the reliability of the results; how far this holds good, and how far culture should be extended, we have at present not sufficient evidence to show. 7. The usefulness of results is probably still further increased by combination of extension of culture with storage in sterilized flasks for a certain time. 8. As regards the control of the working of sand-filtration at water-works, *any* bacteriological test, to be of practical utility, should be repeated at intervals certainly not exceeding a fortnight. 9. It is desirable for the purpose of such control to test the water entering and leaving each filter.

INTERMITTENT OR SO-CALLED CYCLICAL ALBUMINURIA.

In an article on this subject, published in *The Lancet*, Dr. George Johnson recalls the well-known fact that in the vast majority of cases of albuminuria the proportion of albumen varies at different periods of the twenty-four hours. In cases of persistent albuminuria associated with structural degeneration of the kidneys, it will commonly be found that the urine passed at bedtime, and which has been excreted after food and exercise, contains about twice as much albumen as that passed before breakfast, and which has been excreted after prolonged abstinence from food and rest in bed. Again, it is common enough to meet with cases in which, while the urine which is passed after resting in bed and before breakfast is quite free from albumen, that which is excreted after food and exercise contains albumen in greater or less amount.

Dr. Johnson insists upon the importance of testing the urine in all cases of intermitting albuminuria at frequent short intervals. He prefers the picric-acid test to all others. The term "cyclical albuminuria," as applied to cases of the above-described kind, he very properly regards as misleading, implying as it does that the morbid condition recurs regularly, without reference to ascertainable and often avoidable influences. It is of the greatest practical importance to ascertain the probable exciting cause in every instance of intermittent albuminuria; for these cases, if neglected, have a tendency to assume a chronic form.

Contrary to a widely received notion, Dr. Johnson does not believe that the condition under consideration has any relation to the period of adolescence. He fails to state anything definite in refutation of this view, however. It is certainly true that this form of albuminuria is oftener seen in young persons approaching adult life, than at later periods. Possibly the greater activity of adolescence may have some influence in bringing about transient albuminuria.

Not long ago we had occasion to point out in these columns that the term "physiological albuminuria" was really a misnomer. Dr. Johnson evidently shares this opinion, for he states that he knows of no such condition. Normal urines unquestionably contain no albumen. And if the absence of other symptoms of disease signifies anything, then Dr. Johnson affirms that the greatest possible amount of albumen in the urine might in many cases be designated physiological.

REGULATING THE SALE OF PATENT MEDICINES.

Professor Chandler, in discussing the subject of the proposed law licensing patent medicines, recently referred to in The Record, said to a reporter of the *Evening Post* that the bill was a good one, but that the proprietors of patent medicines are too strong for it. This was the view which we took of the matter. It is a question of might against right; and might will prevail, unless, perchance, the medical profession will gird its loins and show the law-makers that it has some fighting qualities in it when a good cause is to be defended. The great trouble lies in the fact that the patent-medicine men practically buy up the local newspapers throughout the State, and they have already written a threatening circular letter intimating that unless the bill against the cause of patent medicines be opposed their advertising patronage will be withdrawn. Small country newspapers live largely on these advertisements, while their readers die largely from them. It is a most unrighteous state of affairs, and one for which there should be a remedy.

THE PRESENT POSITION OF EVOLUTION.

Apropos of the publication of the "Life and Letters of Charles Darwin," *The Lancet* devotes some space to a discussion of the present status of evolution. It points out that evolution is still merely an hypothesis, and not an established doctrine. It says that, for the present, "the attitude of the scientific world is one of almost universal acceptance of evolution as a working hypothesis of unparalleled value and suggestiveness, but of reserve toward it as regards its final issues and ultimate limits. Whatever may be the final form assumed by the doctrine of evolution, we owe an immense debt to Darwin for having unlocked some of the most mysterious recesses of nature and shown us the way of future hopeful advance. His teaching has been of untold value in bringing order into the chaotic mass of scientific material, and in suggesting methods of inquiry which have proved most fruitful and profitable. In physiology, especially embryology, and in pathology, its value has been altogether incalculable. To withdraw the conception of evolution from the domain of science would now seem to us quite as impossible as to return to the Ptolemaic system of astronomy. Just as Newton bound the spheres together by his great hypothesis, so Darwin has succeeded in uniting in one the multiform phenomena of life. If, as has been said, 'the end of science is the detection of unity,' few doctrines have so just a claim to be reckoned scientific as the doctrine of evolution."

Speaking next of the opposition to evolution, *The Lancet* observes that this "has been due in no small measure to a mistaken notion as regards its correct interpretation. It has been often forgotten that it explains processes, not origins; that it elucidates the *method* of creation, but has no explanation to offer as to its *cause*. The recognition of evolution leaves the argument for and against a Creator just where it was, although it undoubtedly modifies our conceptions of his modes of operation. It was one of the chief merits of Comte as a thinker that he clearly perceived that science could only explain processes and transitions, and was unable to grapple with the question of causes. Hence, quite consistently, he ruled out all inquiries into causes as unscientific. In like manner the doctrine of evolution, correctly understood, has nothing to say about causes, and the evolutionist can have just as elevated a conception of a First Cause as the man who vaguely misapprehends evolution as a sort of substitute for a Creator."

It is certainly a favorable sign of the times that questions of this kind can at present be discussed in a spirit of calm inquiry, which alone permits us to see things in their true light. Not many years ago, so much sentiment and so many bitter personalities were always mixed up in bringing matters of this sort before the public that amid the harsh strife of controversy the real questions at issue were commonly lost sight of. Evolution does not run counter to religion, as was formerly asserted. On the other hand, evolution does not explain all things. There may be a healthy atmosphere permeated as well by a scientific appreciation of the one as by a spirit of dignified tolerance of the other. In other words, evolution and religion are not incompatible, but may actually become adjuvants in the endeavor of humanity to grasp truth.

FAILURE OF THE HEART IN VALVULAR DISEASE, AND ITS TREATMENT.

The last few years have witnessed a gradual change in our ideas on the subject of cardiac diseases. The opinion is now firmly rooted in the minds of the advance-guard of the profession, at least, that cardiac murmurs are often devoid of the grave significance that was formerly always attributed to them. So, too, we have come to learn that considerable damage to the valves may be so thoroughly compensated by hypertrophy that it seems permissible to speak of recovery from organic disease of the heart. True, the anatomical lesion persists. But the individual thus affected may live for years, without impairment of his health, and with a working capacity in no way reduced from his normal standard.

It is a very decided step in advance if we are able to state positively that organic cardiac disease is not *per se* fatal. How often, in the past, the doom of some poor sufferer has been sealed by the gloomy prognosis of the physician, will probably never be known. But the time has now come when the "prognosis of despair"—a prognosis from which there was scarcely an exception in former years—must make way for the modern doctrine of hope in the possibility of a cure. What was formerly equivalent to a sentence of death may be commuted then to carefulness for life.

One of the most noteworthy contributions to modern cardiology appears in *The Practitioner* of January, 1888. Dr. J. Mitchell Bruce, the author of the article in ques tion, points out that the subjects of *perfect compensation* of valvular disease are devoid of morbid symptoms. Cardiac hypertrophy, while indicating disability of the heart in some respects, denotes at the same time that nature has made up for this disability by supplying added force to the muscular mechanism of that organ.

From this point of view we can readily agree with the author when he says: "We search anxiously for hypertrophy, we welcome its oncome, we work to establish and maintain it."

When, however, in these cases of perfect compensation, symptoms of cardiac distress arise, we are warned that "failure of the heart" is setting in. We no longer regard these symptoms as due to the valvular lesion *per se*, but as brought about by failure of the cardiac wall.

Careful treatment of this condition may often remove the parietal weakness, and when we have succeeded in doing this, we say that compensation is re-established. The patient then enters upon a fresh period of freedom from symptoms, although the valvular disease itself remains unchanged.

Now, Dr. Bruce argues that "if cardiac failure make its appearance in chronic quiescent valvular disease, it must have originated in some conditions or circumstances unfavorable to compensation; and prognosis and treatment, to be sound and successful, must be framed on a full knowledge of what these conditions or circumstances are." He does not refer to the necessity for a general acquaintance with the causes of broken compensation, but to the application of this knowledge in each individual instance of cardiac failure that comes before us. In his experience it is "by no means common for the physician to inquire into the causes of cardiac failure in every case that seeks his advice." When a patient with palpitation, dyspnœa, cough, and threatening dropsy presents himself for treatment, he doubts "whether we are always careful to put the question to ourselves—What has happened to this man that he should come to me with these symptoms after twenty years of freedom from suffering since the original rheumatic endocarditis? Time was when we were satisfied in such a case with the diagnosis—mitral incompetence. We should now consider this diagnosis as insufficient, and would complete it by saying—mitral incompetence with cardiac failure." He ventures to say that "this diagnosis is still short of the full truth, and that when we proceed to offer a prognosis based on such a conclusion only, and to apply treatment, we proceed on insufficient information. We must first determine the *cause of the failure*, why the heart has broken down—whether from muscular strain, or nervous exhaustion, or alcohol, or other discoverable cause." He maintains that until this point is satisfactorily settled we are not justified in offering a forecast or ordering a therapeutical course.

Dr. Bruce next proceeds to consider the most frequent causes of broken compensation. According to him, they may be described as follows: 1. Muscular overwork. 2. Nervous causes, such as the depressing emotions of fear, grief, distress, and anxiety. Worry, here as elsewhere, is potent for much mischief. Nervous excitement of a pleasurable kind may also work evil. 3. Imperfect blood-supply to the heart. This may result from general hæmatic impoverishment, or from a diseased state of the coronary arteries. 4. Intercurrent diseases, among which rheumatism and pulmonary mischief are most to be dreaded. 5. Causes peculiar to women, such as pregnancy, confinement, protracted lactation, the climacteric, or even difficult menstruation. 6. The every-day use of tea, coffee, tobacco, and alcohol, which act, according to Dr. Bruce, as cardiac poisons. 7. Increase of the valvular lesion, due to endocarditis, rupture of a diseased valve, etc. 8. The advent of what may be called the "limit of compensation." By this is meant the limit that is placed on life and health by the occurrence of secondary changes in the lungs, liver, kidneys, and indeed in the cardiac wall itself. Cardiac dropsy is finally developed. Judicious treatment "may again and again secure for a time a fresh accommodation, a new adjustment of the physiological balance; but the end cannot be indefinitely averted—the limit of compensation is finally reached."

Sound treatment must be based on a sufficient knowledge of pathology, and also on correct views concerning etiology. Dr. Bruce utters these warning words, in which we heartily concur: "Do not treat cardiac disease without sufficient evidence that treatment directed to the heart is required. Let us be sure that the heart is failing before we proceed to apply our remedies. The day has gone by when men with any pretension to therapeutical judgment did not hesitate to treat murmurs—when they ordered digitalis and iron, let us say, for a mitral *bruit* which they happened to discover in a dyspeptic patient. If the heart is really failing, and treatment called for, do not apply treatment in a routine fashion. Cardiac failure is but an effect: rational treatment begins with attention to the cause. We must discover the cause of the break-down, and remove it if possible. Our means of treatment will vary widely in different cases. We have an extensive choice of remedies. We are not confined to a few routine methods or a few habitual drugs, but can turn to account every means hygienic and therapeutic that is suggested by faithful investigation and sound judgment. This is a very encouraging consideration. The poor overworked, half-starved laborer must be ordered rest and warmth and food in hospital. The sedentary free-liver requires the very opposite line of treatment—he must be sent to climb mountains or to hunt, to endure for a time the miseries of palpitation and breathlessness, if compensation is to be successfully restored. We treat intercurrent rheumatism with remedies—such as salicylates—calculated to quickly dispel it. We interdict the consumption of cardiac poisons. We remove the overworked, ill-fed, anæmic girl from business in town to the country."

Of course, there will always remain a certain proportion of cases of heart-failure in which the cause is not discoverable. Here a rational symptomatic therapy is alone indicated. The balance of circulation is to be restored as quickly as possible by such direct cardiac remedies as digitalis, strophanthus, or convallaria. But even here the general condition of the patient is not to be lost sight of, and what hygienic surroundings, rest, and proper nutrition can do is never to be underestimated.

THE NEW ANÆSTHETIC ERYTHRO-OPHLŒINE has been tested by Mr. John Tweedy, of London, who writes to *The Lancet* that the drug is irritating and has very little anæsthetic effect.

News of the Week.

Death of Dr. F. R. S. Drake.—Medical circles were much shocked to learn of the sudden death, on March 11th, of Dr. F. R. S. Drake, at the age of forty-three years. Dr. Drake was very widely known and esteemed by the profession of this city. He was born in Windsor, Conn., and graduated in medicine at the University Medical College in 1871. He became associated with Professor Lerrius, and for some time had been Professor of Clinical Medicine at the University, and Visiting Physician to Bellevue Hospital. He was a member of the County Medical Society, at one time being a vice-president. He was Chairman of the Board of Censors, and was very active in securing the medical legislation of the State as member of the Legislative Committee of the Medical Society of the State, of which committee he was a member for two years. He was also a member of the Academy of Medicine, the Pathological Society, and a prominent mason, having been a Deputy Grand Master and a member of Prince of Orange Lodge. For a while he was Secretary of the Alumni Association of the Medical Department of the University of New York.

Bellevue Hospital Medical College held its annual commencement at Carnegie Laboratory on the evening of March 12th, during the time of the great blizzard. The diplomas were bestowed, and then class and faculty made their way to the Hotel Brunswick and celebrated with a supper.

The Long Island College Hospital held its twenty-ninth annual commencement on March 9th, graduating a class of thirty-six.

The New Asylum for the Criminal Insane.—The proposed asylum buildings for insane criminals, for which the Legislature appropriated $185,000 recently, are to be located about one and one-quarter miles east of the villages of Matteawan and Fishkill, Dutchess County. The hospital buildings proper will number ten, consisting of six pavilions of ward buildings, two infirmaries, and two isolated buildings planned especially for the most dangerous and vicious class.

The American Veterinary College held its thirteenth annual commencement on March 1st, and graduated a class of thirty-two.

Dr. Thomas D. Swift died in this city last week. He was graduated at the College of Physicians and Surgeons in 1879, and had practised here since that time.

The Emperor of Germany.—Medical opinion in England, and perhaps this country, is inclining to the belief that the Emperor of Germany has only a perichondritis, and may get well.

The Blizzard almost paralyzed medical work for a day or two, both in private practice and at hospitals. It was with great difficulty that ambulances could be sent out, even on Tuesday.

New York College of Dentistry.—The twenty-second annual commencement of the New York College of Dentistry was held at Chickering Hall, Saturday evening, March 10th. Seventy-two graduated. The address was delivered by Rev. Dr. Gallaudet.

Measures for the Antiseptic Treatment of the Throat in Diphtheria.—1. M. Gaucher's method is to rub the affected surface with a cotton-covered probe soaked in an alcoholic solution of camphor and carbolic acid. This is done twice daily. In the intervals the parts are washed with a one per cent. solution of carbolic acid.

2. The method of Bouffé is to give one teaspoonful, every two hours, of the following:

℞. Lemon juice		300.0 grammes.
Sodæ sulphat.,		
Sodæ chlorid	āā	5.0 "
Ferri saccharat		3.0 "
Sodæ phenat		♏ xxv.
Mel		3.0 grammes.

M. The same solution is used as a gargle.

3. The treatment suggested by Osicki is to paint the parts with the following:

℞. Tinct. rhatan	10.0 grammes.
Tinct. benzoin	5.0 "
Tinct. aloes	3.0 "

M. After each application the following powder is insufflated:

℞. Sulphur. precip.,		
Potas. chlorat	āā	5.0 grammes.
Tannin		1.5 "

M.

4. The so-called combined antiseptic treatment consists of painting the parts four times daily with an alcoholic solution of corrosive sublimate, 1 to 1,000. In the intervals the parts are irrigated with a one per cent. solution of boric acid. Internally there is given every hour a teaspoonful of the potion of Letzovich. The formula for this is:

℞. Soda benzoat	5 to 15 grammes.
Aquæ q. s. to dissolve.	

To this add:

℞. Aquæ menth. pip	50.0 grammes.
Syr. aurant. cort	10.0 "

M. With the above is given plenty of alcohol internally.

The Address before the Alumni of Bellevue Hospital.—The first annual address before "The Society of the Alumni of Bellevue Hospital" will be delivered at the Academy of Medicine, on Wednesday evening, April 4th, at half-past eight o'clock, by Dr. Wm. T. Councilman, Associate Professor of Pathology in the Johns Hopkins University; subject, "Predisposition in Tuberculosis." The profession of the city are cordially invited to be present.

Correction.—Dr. H. J. Garrigues writes: "On page 281 of the last issue of The Medical Record, in a report of my paper on 'Laparotomy for Rupture of the Uterus,' I find the statement that as many as thirty-seven sutures were necessary to *prevent* folding-in of the peritoneum. Will you kindly insert a correction to the effect that the reporter has misunderstood me. The numerous sutures were necessary in order to fold the peritoneum in between the edges, so as to apply one serous surface against the other, which gives the most rapid agglutination."

STATE MEDICAL SOCIETY OF ARKANSAS.—The Thirteenth Annual Session of the State Medical Society of Arkansas will be held at Fort Smith, Ark., Wednesday, Thursday, and Friday, April 25, 26, and 27, 1888, commencing on Wednesday at 11 A.M.

NEW YORK HOSPITAL.—At a meeting of the Governors of the New York Hospital, March 6th, Drs. A. B. Ball and E. L. Partridge were elected Attending Physicians and L. A. Stimson Attending Surgeon.

MEDICAL STUDENTS' DUELS.—The custom of duelling, which still survives with astonishing pertinacity among German students from one generation to another, has recently given rise to two sad accidents in Berne. One of the combatants had the whole of his nose slashed off, while another, who was on the point of taking his M.D. degree, had his right arm so entirely disabled by a foil that his medical career has come to a premature end. These accidents, however, did not prevent another series of duels, which took place on February 4th (that is, a couple of days after the above-mentioned accidents), in Berne, between several members of the Corporation Helvetia and as many students from the University of Zurich, who had come to Berne expressly for the purpose.

"L'ÉLECTROTHÉRAPIE" is the title of a new journal devoted to electro-therapeutics, and published in Paris under the editorship of Dr. Léon Danion.

THE PHILOSOPHER can draw an interesting moral from the following tale of the revolt of the Cyprians at Naples. Seven hundred women, suffering from venereal diseases, were under treatment at a large charity hospital devoted to such kinds of disease. It was found that lovers, who must indeed have been ardent, came to visit the patients under the guise of parents, etc. The visits were forbidden, whereupon the patients rose in revolt, turned out the authorities, defeated the police, and only succumbed to military force.

"THE CLIMATOLOGIST" is the name of a new quarterly journal published in Washington, and edited by William C. Chase. Its mission is "public, not technical."

THE CONSTITUTIONALITY OF THE LAW REQUIRING LICENSING OF DENTISTS IN INDIANA was recently affirmed by the Supreme Court of that State.

PROGRESS IN SANITARY LEGISLATION IN 1887.—In Vermont a State Board of Health has been organized. In Wisconsin the powers of the State Board have been extended and its relations to local boards more clearly defined. In Alabama a special quarantine fund has been appropriated. In Michigan a laboratory of hygiene has been established in connection with the University of Michigan. In Ontario the provincial board has power to act as a local board in the absence of such an organization, and in emergencies. In New Jersey laws have been passed creating a *per capita* tax for health purposes. In West Virginia laws have been passed extending quarantine to cattle, making county boards of health less medical, licensing medical practitioners, and establishing a system of vital statistics. In Illinois a law permitting cities to maintain abattoirs has been declared constitutional. In Kentucky efforts are being made to secure a law prohibiting adulteration of food. In California a special quarantine fund of $25,000 was created. In New Hampshire health authorities have been given power over slaughtering and rendering establishments, permitting them to close polluted wells, and to close up dwellings in bad sanitary condition. Physicians must report all cases of scarlet fever and diphtheria to the local board of health. —*Sanitary News.*

DR. WILLIS W. FRENCH died at his residence in this city, on March 11th. Dr. French was a native of Portsmouth, N. H. He graduated at Bowdoin College in 1878, and studied medicine and was graduated at the New York College of Physicians and Surgeons in 1883. After getting his diploma he went West, but returned to New York in 1886 and was connected for a time with the Board of Health.

THE CODE OF ETHICS AND THE OATH OF HIPPOCRATES. — The suggestion is made that physicians be obliged to subscribe to the Oath of Hippocrates, instead of the Code of Ethics. This oath is a noble piece of writing, and shows that the ideas of the moral dignity of the profession of medicine were as great two thousand years ago as now. Barring the matter of gods and goddesses, the educational methods, and the cutting for stone, the doctor who followed its injunctions could not fail to lead an honorable life. It may interest our readers to read this ancient document again: "I swear by Apollo the Physician, by Æsculapius, by Hygeia, and Panaceia, and all the gods and goddesses, calling them to witness that I will fulfil religiously, according to the best of my power and judgment, the solemn promise and the written bond which I now do make. I will honor, in the same degree as my parents, the master who has taught me this art, and endeavor to administer to all his necessities. I will consider his children as my own brothers, and will teach them my profession, should they express a wish to follow it, without remuneration or written bond. I will admit to my lessons, to my discourses, and to all my other methods of teaching, my own sons, and those of my tutors, and those who have been inscribed as pupils and have taken the medical oath, but no one else. I will prescribe such a course of regimen as may be best suited to the condition of my patients, according to the best of my power and judgment, seeking to preserve them from anything that might prove injurious. No inducement shall ever lead me to administer poison, nor will I ever be the author of such advice; neither will I contribute to an abortion. I will retain religiously the purity and integrity both of my conduct and of my art. I will not cut anyone for the stone, but will leave the operation to those who cultivate it. Into whatever dwellings I go, I will enter them with the sole view of succoring the sick, abstaining from all injurious views and corruption, especially from any immodest action toward women or men, freemen or slaves. If, during my attendance, or even unprofessionally in common life, I happen to see or hear of any circumstances which should not be revealed, I will consider them as a profound secret, and observe on the subject a religious silence. May I, if I religiously observe this oath, and do not break it, enjoy good success in life, and in the practice of my art, and obtain general esteem forever; should I transgress and become a perjurer, may the reverse be my lot."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 1, 1888.

Abraham Jacobi, M.D., President, in the Chair.

Dr. Edward B. Bronson read a paper entitled,

SHOULD WE TREAT SYPHILIS DURING THE PRIMARY STAGE?

By preventive treatment was not necessarily meant abortive treatment, but measures which abridged the course and ravages of the disease upon the constitution. To carry this out most intelligently it would be desirable to know the essential qualities of syphilis, but of this we had not yet any knowledge. But the question as it now presented itself to us was, Are the indications thus far afforded by our imperfect knowledge of syphilitic affection such as to render any attempt at preventive treatment in the primary stage of the disease unavailing and absolutely helpless? For that is what many maintain.

There were two modes of approaching the question, the one theoretical and the other clinical; in the former the first inquiry was directed to the essential cause of syphilis, called the syphilitic virus. Here all was hypothetical. No theory so satisfactorily explained it as that which attributed it to the presence and growth in the tissues of a specific micro-organism. But this had not been demonstrated. If it could be established, it was by no means certain that preventive treatment would then prove successful. The efficacy of antiseptic methods was far from insured, even in those diseases which had been traced to a known micro-organism.

The author said all facts seemed to point to a local affection in the beginning; there was a temporary sojourn of the virus in the region where it was first implanted. Local manifestations remained for a considerable period the sole evidence of the disease. Later, constitutional symptoms manifested themselves. From here the virus sooner or later contaminated the neighboring lymphatic glands, and then passed to the general system. Whether several lymphatics were affected simultaneously in the beginning had not been determined. Those who claimed that the disease was constitutional from the beginning offered as proof of this that immediately after infection the person obtained immunity from subsequent inoculation; that this immunity took place before the chancre developed; also, that extirpation of the chancre had not prevented advance of the disease. There was reason to believe that the virus soon passed beyond the reach of the cautery or the knife. The case of Berkley Hill was cited in proof of this view. It could not be said that the results of excision were conclusive either for or against the hypothesis of a local affection at the commencement. Nor would want of success prove that the syphilis was not at first local.

If the disease was in the beginning a local affection, what hope was afforded by preventive interference? Empirically the answer was so ambiguous that we were forced to fall back on theory. In the first stage of syphilis most authorities advised only expectant treatment. But, the author asked, must all the virtues of that wonderful drug, mercury, be waited for until after the appearance of the second stage of syphilis? Were there no other resources during the first stage except excision of the initial lesion, and, as some had advised, the internal administration of mercury and iodide of potassium? Excision of the initial lesion was proper when practicable, but it was a question how far it should extend, how many glands should be excised, and its efficacy could only be surmised. But it was desirable that these experiments be continued. With regard to medicinal treatment during the primary stage, it had been claimed that it delayed the appearance of the later symptoms, while it had also been claimed that when they did appear they were more severe than when treatment had not been instituted during the primary stage. It seemed to the author that there was a singular inconsistency in using mercury so freely during the secondary stage in those who believed syphilis was general from the commencement, and yet opposing its use during the primary stage through fear of rendering tertiary symptoms, should they develop, more severe.

But it appeared to Dr. Bronson extremely doubtful whether during the primary stage the local affection could be reached by internal medication; the local use of mercury seemed to him more rational. Yet, if the disease was due to a micro-organism, it was not unreasonable to suppose that mercury might be efficacious through its germicidal qualities. Although mercury might act as an antiseptic in syphilis while the disease was local, yet it was very doubtful whether it would have such an effect after the virus had entered the blood. Mercury was more likely to exert its peculiar influence when syphilis was a topical disease.

The primary object of his paper was to call attention to the more direct employment of the bichloride in the region where the chief source of danger had its seat. It was purely on theoretical grounds that he recommended this method. The scheme was to bring mercury in contact with the region of the infection during the primary stage. The field of operation might extend to all those glands which might be supposed to be the channel through which the virus found its way to the general system—the inguinal and iliac glands, and the glands on the upper thigh. It was rational to suppose that the mercury used by inunctions or injections at this stage might destroy the germs or hinder their progress. When an injection was used, it was unnecessary to employ more than $\frac{1}{100}$ of a grain. As an inunction, mercurial soap was preferable to mercurial ointment.

The author thought that this treatment, although based on theoretical grounds, was better than to let the patient go away without any hope until the disease should break forth as a constitutional affection.

Dr. E. L. Keyes said he would have been much more interested in the proposed plan of treatment had the author given his results. Had such a course been in any way beneficial?

Dr. Bronson said that if his paper had any virtue at all, it was that it did not try to give results of treatment. The conditions made it very uncertain and difficult of practice, and considerable experience would be required to enable us to judge of its merits. He had attempted to employ it in several cases, but in some the patients failed to carry it out, in others there was uncertainty of diagnosis, in all, some weeks had elapsed since the suspicious connection.

Dr. Keyes had never tried this method, but he would be willing to do so if the results obtained by others were encouraging. But it seemed to him that after the initial lesion had manifested itself, the disease was beyond the reach of local applications. His own impression had always been that syphilis became general from the first, before the appearance of the primary lesion, which formed after a period of incubation. Perhaps he could not prove the correctness of this view, but the contrary had not been proven to his satisfaction. Dr. Keyes referred again to a case in which he extirpated an initial lesion about twelve hours after its appearance, yet the man went on to have the secondary symptoms in a most marked degree. The wound made during excision healed, and no ulceration or induration occurred subsequently.

The objection to the treatment of the primary sore with the only remedy which was customarily relied upon as being capable of attenuating, modifying, or more or less doing away with the subsequent symptoms, namely, mercury, until the diagnosis of syphilis had been confirmed by subsequent lesions, consisted in the fact that more or less discord was thereby thrown into the whole life of that patient. He had seen a number of such cases, and they had confirmed him in the belief that it was best never to treat syphilis until one was satisfied of the diagnosis.

Dr. R. W. Taylor thought with Dr. Bronson, that the history of the syphilitic sore and the analogical evidence offered by other diseases, like cancer and tuberculosis, and the knowledge which we were acquiring regarding the action of bacteria, went to show that at first syphilis was a local affair, but unfortunately we did not know how far it was local. He thought extensive experience had shown that neither cauterization nor excision of the initial lesion would remove the virus. But he thought Dr. Bronson's idea was a most laudable one, and if this terrible disease could be strangulated from the first, we should use every rational means to that end. It was his opinion, however, that this could not be done, for the reason that we could not reach all the affected cells which lay in the adventitia of the blood-vessels and lymphatics. He did not believe there was a single case of true syphilis which had ever been aborted by excision or cauterization, and he had read the reports of all the cases in medical literature. Dr. Taylor believed the mother could bear a syphilitic child without herself acquiring the disease, the father having transmitted the disease to the offspring; but he also believed she could afterward acquire syphilis in the regular way. The bearing of a syphilitic child, he thought, gave her no immunity.

There was good reason for employing very active treatment, as by injections and inunctions of mercury, when constitutional syphilis became manifest; it required a most powerful remedy, and it was necessary to bring the remedy into immediate contact with the syphilitic cell-formations in order to destroy them. In the region in which the mercury acted immediately the papules disappeared in about half the time of those on which it operated mediately. The suggestion made by Dr. Bronson, to get the local effect of the bichloride solution, would have greater weight if he had not employed so mild a solution. In order to get a good effect large doses must be used; yet hypodermic injections of bichloride solution in fair strength about the legs would always produce abscesses. Such had been his experience.

It was Dr. Taylor's opinion that to treat syphilis in the primary stage was to make it disorderly. If the disease were allowed to take its regular course until the development of secondary symptoms, until the appearlance of the rash, the man would then be satisfied that he had the disease, and would prove tractable; but if he had not seen such symptoms he would be likely to disobey all instructions, go on and drink and carouse, and refuse in every way to aid the physician in his efforts at cure. The sickening smile which came over the man's face on seeing the general rash of syphilis, and which Dr. Taylor called the syphilitic countenance, was a sure sign that his spirit had been humbled. There were some cases in which early treatment could only with difficulty be avoided, as when a man wished to be "fixed up" before his wife returned home. He believed mercury acted by producing fatty degeneration of the syphilitic cells. These had not developed all over the body until the appearance of constitutional symptoms; then why begin to dose for a condition which would not appear until thirty days later? There was evidence to prove that syphilis did not run as tractable a course in those who were early medicated as in those whose treatment dated from the general manifestations.

Dr. Leónard Weber had promised to read a paper on regional treatment of syphilis. This he postponed, but he expressed his agreement with the majority of writers that it was not desirable to institute constitutional treatment until the disease had thoroughly manifested itself.

Dr. Bronson closed the discussion. He claimed that the subject which he had raised for discussion was one which must be approached from a speculative standpoint before facts could be developed. He had only tried to point out possible indications with the hope that the treatment might be forthcoming, that the trial might be instituted. Patients thought the argument, that if the disease were treated in the beginning it would become disorderly in the future, was only worthy of derision; they would not accept such an excuse for refusing to institute treatment at once. He had seen no thickening or ulceration follow injections in the neighborhood of the thigh and inguinal region when the mercurial solution had been of the strength mentioned, and which he regarded sufficiently strong to produce the antiseptic effect.

The President apologized for making some remarks after Dr. Bronson had spoken, and said some of the difficulties in this line of study might be stated as follows: 1, The length of time required before the secondary symptoms became manifest was uncertain; 2, we did not know what amount of poison, or the nature of the poison which had been introduced; 3, we could not tell what was the exact change in the lymph vessels which had carried the poison into the general system.

Some of these points could be best illustrated by comparisons with what had been seen in certain infectious diseases, as in diphtheria. We knew that diphtheria was local; that it might remain local, or it might become constitutional very soon. It remained local when it was in a neighborhood in which there were very few lymphatic vessels, as on the tonsils. But when it appeared in the posterior nares the disease became constitutional at once, and manifested itself in enlarged glands at the angle of the jaw. Constitutional infection did not always take place to the same extent. Why was this so? Because, he replied, the lymphatics differed in different persons and at different ages.

Again, there were some cases of nasal diphtheria in which there was not much swelling of the glands near the angle of the jaw, but the poison seemed to enter the general circulation in a more direct way than by the lymphatics; it seemed to go directly into the blood. Such patients often died in a few days after the development of diphtheria. The President thought the action of the syphilitic poison might be analogous to that of diphtheria.

THE TREATMENT OF FLAT-FOOT,

was the title of a paper sent by Mr. Bernard Roth, F.R.C.S.E., and read by Dr. Gibney (see p. 289).

Dr. Ridlon approved of the use of the Thomas shoe and of gymnastics in flat-foot. It had been claimed in this country that one cause of the deformity was spasm and contraction of the gastrocnemius, and stretching of that muscle had been resorted to. Dr. Ridlon believed this spasm and contraction, when they occurred, were preceded by the foot deformity, and that the deformity was not the result of the muscular contraction. Regarding pads and springs worn under the foot, they might relieve tenderness and pain for a time, but they did not cure the deformity, and when the patient once began using them he found it necessary to continue their employment.

Dr. A. M. Phelps treated valgus by putting the patient under the influence of an anæsthetic and forcing the foot into a desirable position, holding it there for a time by a plaster-of-Paris splint, and repeating the procedure as might be necessary. In this way, placing the foot in a position to get the weight of the body transmitted through the arch in another direction, and then allowing the ligaments time to regain their normal strength, as much could be done as could be expected in valgus. An apparatus for accomplishing this object was described. In certain cases in which there was want of muscular development the use of massage and electricity was indicated.

On motion of Dr. Agramonté a resolution was taken from the table and passed, petitioning Congress to remove the import duty on all medicines and surgical instruments and apparatus.

SECTION IN SURGERY.

Stated Meeting, February 13, 1888.

R. F. Weir, M.D., Chairman.

EXCEPTIONAL FRACTURE AT THE LOWER EXTREMITY OF THE HUMERUS.

Dr. Charles A. Powers presented a boy, aged eleven, who, April 24, 1887, fell from a wagon, striking on the inner aspect of the left elbow. Immediately thereafter he sought treatment at the Chambers Street Hospital. There was found to be almost complete disability at the elbow, very much pain, and moderate swelling at the inner aspect of the joint. There was no fracture through either condyle nor through their base, and the ulna was intact. There was no difference in the contour of the epicondyles when the elbow was carefully compared with its fellow.

Between the internal epicondyle and the inner aspect of the olecranon lay a loose body about the size of a bean; it was freely movable and could be made to grate on the adjacent bone. When the ulna was firmly grasped antero-posteriorly at the coronoid process it could be made to slip internally on the humeral trochlea, and in so doing carried with it the loose fragment. The inner ridge of the trochlear surface could not be felt. The examination was made under ether.

From the preservation of the contour of the internal condyle, and the free lateral motion of the ulna, Dr. Powers concluded that this fragment could come only from the inner trochlear surface of the humerus.

The forearm was placed at ninety degrees, midway between pronation and supination, and a plaster-of-Paris splint applied which was kept in place four weeks, at the end of which time the condition noted was as follows: Moderate thickening at the inner aspect of the humerus below and without the internal epicondyle, flexion to eighty degrees, extension to one hundred and twenty degrees, pronation and supination almost complete.

The patient was directed to poultice, bathe, and massage the elbow. The functions gradually returned, and six months later all were complete except extension, which was some ten degrees short of normal.

Dr. Powers called attention to the fact that there was an independent epiphysis for the trochlea, and the question was raised whether this might not have been a separation of that epiphysis.

The Chairman thought the lesion was a rare one. He had had no experience with it.

Dr. Powers also presented two cases of

PRIMARY EXCISION OF THE ELBOW.

The first was that of a man, aged twenty-three, who was brought to Chambers Street Hospital, April 23, 1887, with a history of having had the right elbow crushed between an elevator and its shaft fifteen minutes previously. The lower end of the humerus was the seat of a compound comminuted fracture. The soft parts were very severely lacerated over the whole posterior, external, and internal aspect of the elbow, from the junction of the lower fourth of the humerus with its upper three-fourths above to a point two inches below the olecranon at the back of the forearm. The musculo-spiral nerve was exposed through three and one-half inches, it was contused, and about one-fourth of its fibres were torn across. The ulnar nerve was exposed, but it was intact. The triceps was completely torn across, and was so severely lacerated that a portion of its lower muscular part, the size of one's fist, required removal. The soft parts were freely stripped up in every direction. The radial and ulnar arteries pulsated. Motion and sensation in the hand and fingers were good. There was slight shock.

Four hours later the fragments of the humerus were removed, and the shaft of the bone was sawn through two and a quarter inches above the external epicondyle. The anterior surface of the olecranon was taken off, and the fresh surfaces wired to the lower end of the humerus with the elbow at ninety degrees. Lacerated tissue was freely cut away, the wound very thoroughly drained in all directions, and packed with an antiseptic dressing. A fenestrated plaster-of-Paris splint was applied over all. Moderate traumatic fever followed. The wound gradually filled with granulations and was skin-grafted from time to time. Three months later there was necrosis of the lower end of the humerus. This was removed, and also the wire. The sinus quickly closed.

Now, ten months after the injury, the patient's condition is as follows: Flexion to seventy-five degrees; extension to one hundred and forty-five degrees; forearm fixed midway between pronation and supination; no lateral motion, and elbow strong.

The second case was shown for comparison by the courtesy of Dr. Bull. The patient was a man, forty-eight years of age, who, March 3, 1883, fell three stories to a floor beneath, striking on the left elbow. Immediately afterward he was taken to Chambers Street Hospital. The olecranon was severely comminuted, one of its fragments protruding from a posterior wound just above the process. There was moderate shock. Stimulants were administered, an antiseptic dressing was applied to the elbow, and twelve hours later the joint was excised through Langenbeck's incision. The ulna was sawn across on a level with the upper surface of the head of the radius. The humerus was found to be the seat of a longitudinal fracture extending into the olecranon fossa, and sawn off at the upper limit of that fossa. Moderate necrosis of both ulna and humerus followed, the wound healed by granulation, and at the end of three months was closed. Motion gradually returned. At the expiration of two years the joint was "flail"-like, yet of considerable strength; the patient could flex strongly, extend fully, pronate and supinate well, yet the bones of the forearm rested above and within the lower end of the humerus, and there was much lateral motion as well as hyperextension.

Dr. Powers thought that a comparison of these cases would show the preservation of the olecranon, possible in the first but not in the second, to be a measure of value, and adding much to the strength of the joint. The humerus was sawn at a higher point in the first case, yet it found an excellent resting-place in the greater sigmoid cavity, and there was at this time no lateral motion.

Attention was called to the fact that in the first case there was very extensive loss of substance in the lower part of the triceps, yet the patient had excellent power of extension; also to the preservation, at the time of the injury, of sensation and motion in the parts supplied by the radial and musculo-spiral nerves, yet the musculo-spiral was partially torn at a point just above its division.

NON-RECURRENCE OF CANCER OF THE LIP AFTER EXCISION.

The Chairman, Dr. Weir, presented a man on whom he operated for cancer of the lip in 1878. There had been no return of the disease. Nearly the entire lip had been involved. The method of operating was that of Burow. He had seen good surgeons fail to take the precaution of so shaping the flap as to have it lined with mucous membrane. Regarding the results of operation in this class of cases, Wörner had collected six hundred and ninety-eight cases, with recovery in twenty-nine per cent., the length of time the patients were under observation after the cancer was removed being at least three years.

Dr. Abbe had removed somewhat more than the entire breadth of the lower lip for cancer once by this method, and once by another, and in neither had there been a recurrence, at least within a year, the operation having been performed four and six years ago. Enlarged glands were removed at the time of the operation.

Dr. A. Jacobi had had two cases of cancer removed by operation, there being no recurrence in either, the operation having been performed, in one case fourteen and in the other twenty-three years ago.

Dr. Robert Abbe read a paper on

GANGRENE OF THE PERINEUM (see page 294);

also one on

DUPUYTREN'S CONTRACTION OF THE FINGERS,

which will be published in THE MEDICAL RECORD.

The Chairman recalled distinctly one instance of gangrene of the ischiatic fossa of the character described by Dr. Abbe, and one other but indistinctly. The first occurred in a large, burly man, subject to constipation. Pain and swelling developed about the anus, and the parts were in the condition illustrated in the diagram of Dr. Abbe's case, except that the dark or gangrenous portion did not extend quite so far in circumference. Dr. Weir made incisions into it; no pus was found. The condition disappeared after a time, and subsequently an opening was found into the rectum. The fistula was divided, and the patient got entirely well.

He had seen a case of gangrene around the rectum, the result of a faulty injection, in an insane patient. The nurse made the injection to relieve constipation, but the patient being analgesic the nurse was not aware that he was making the injection not into the rectum but into the surrounding cellular tissue. The patient's life was saved with difficulty. Dr. Weir also cited another similar case which occurred at the New York Hospital when he was house-surgeon.

Regarding the cause of the gangrene in the class of cases described by Dr. Abbe, the Chairman thought it probably originated in certain germs.

Dr. A. Jacobi had not seen any cases of gangrene of this form, but he thought it might be compared with advantage with other forms of gangrene. Local gangrene would result from insufficient circulation and nutrition of the parts. This he thought might take place, although it seldom did, around the rectum as well as in parts most remote from the centre of circulation—the usual seat of gangrene of this form. Persons who lived a sedentary life, and were subject to constipation, were more likely to develop proctitis and periproctitis than were others, because of interference with nutrition of the parts; there was partial obstruction with emigration of leucocytes. If this obstruction went further, gangrene might result. The obstruction was more likely to result from thrombosis than from embolism, as in the latter case one would expect the circulation to be carried on through the very free anastomosis here present. He did not think it was necessary to resort to the germ-theory to explain these cases.

Dr. Weir thought Dr. Jacobi's explanation of the cases would not necessarily preclude the influence of germs in the causation of the disease.

Dr. Weir had formerly believed more or less fully in the gouty or rheumatic origin of Dupuytren's contraction of the fingers, but Dr. Abbe's experience went far to prove a nerve-origin.

Transmission of Tuberculosis by the Respiratory Passages.—From experiments recently made on animals, MM. Cadéac and Mallet have shown that the respiratory passages are very favorable seats for the development of tuberculosis when the bacilli which penetrate to their interior are conveyed in distilled water or an inert liquid. The development of the bacilli, however, finds no encouragement if the respiratory passages be sound and the bacilli conveyed in the dust. The net result of their experiments goes to show the importance of preventing simple catarrh of the respiratory passages. It would seem as though irritation of the air-channels and the presence of tubercular bacilli were the only two necessities for the development of tuberculosis. The animals experimented with were rabbits, notoriously subject to tubercle; so that it is possible that there must be a proper soil for the growth of the bacilli, as well as some simple lesion affording a point of entrance for them into the system.—*The Lancet.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MR. HUTCHINSON ON THE ABORTIVE TREATMENT OF SYPHILIS—THE WATER-SUPPLY OF LONDON—ALCOHOL AS A PATHOLOGICAL FACTOR—A POST-GRADUATE COURSE FOR DENTISTS—PROPOSED ROYAL COMMISSION ON HIGHER EDUCATION IN LONDON—INSANITATION AT THE BROMPTON CONSUMPTION HOSPITAL.

London, February 29, 1888.

Mr. Jonathan Hutchinson has long been an earnest advocate for the plan of treating syphilis by means of a prolonged course of mercury given in small doses. Gray powder is the preparation which he prefers, given three times a day, in doses of a grain. At the last meeting of the Medical Society of London he read a paper entitled "The Abortive Treatment of Syphilis," in which he laid down the proposition that it is quite possible by the early and continuous use of mercury to suppress the secondary stage of syphilis, or, at any rate, to greatly modify it. In very few cases in which mercury had been used without interruption has he seen a well-marked secondary eruption or a typical sore throat. He remarked that he thought all were agreed that characteristic and considerable induration always yielded quickly to the influence of mercury; that high temperatures in syphilis always abated under its influence, and that in cases where a patient had had no treatment until his eruption was well out the use of mercury would usually cause the eruption to vanish. If these propositions were true, he did not see much improbability in the assertion that mercury would prevent the development of the fever and eruption, if administered and steadily continued, before they showed themselves. As regarded tertiary symptoms, abortion was quite another matter. It was possible that in our present modes of using mercury we neither began early enough nor continued long enough to secure that result. There was a sense in which tertiary symptoms might be said not to be syphilis at all. There was neither proof nor probability that the microbe or virus was present in their lesions. They did not develop symmetrically, and were not contagious. They were due to processes of inflammation occurring in tissues which had formerly been under the influence of syphilis and had been modified by it. Returning to the question of the abortive action of mercury, Mr. Hutchinson observed that he had notes of many cases in which a patient came under his care with a well-indurated chancre, he advised a long course of small doses of mercury, the induration melted away, and nothing else followed so long as he had been able to observe the patient. He remarked that he had seen scarcely any eruptions in those for whom he had prescribed during the primary stage, and of really troublesome eruptions, such as were common enough when mercury had not been used, he might confidently say that he had seen none.

Some discussion followed Mr. Hutchinson's paper. Mr. Astley Bloxam remarked that the great question was, whether the patient had syphilis or not. An experience of ninety thousand cases had led him to conclude that induration was quite without value in the diagnosis. Only a general and symmetrical enlargement or hardening of the glands sufficed to place this beyond a doubt. As to treatment, he preferred subcutaneous injections.

Mr. Marmaduke Sheild asked Mr. Hutchinson's opinion of the merits of excision of the primary sore. Mr. Malcolm Morris suggested that, as induration of the glands indicated elaboration of the poison, the early administration of mercury might really (by stimulating metabolism) aid in the prompt dissemination of the virus. In replying, Mr. Hutchinson maintained that the character of the sore afforded much more information toward making a diagnosis than the glands, as to which he had often been in doubt. In his experience, well-marked induration of the sore meant syphilis, but many specific sores did not show this induration. Mr. Morris' views required to be put to the test of experience. Excision of the sore might be desirable whenever practicable, but its influence would depend largely on the site and age of the sore. When once the induration was marked the system was infected.

One of the metropolitan water companies is seeking parliamentary powers to transfer its intake from the Thames to a point about twenty miles up the river. As, however, they propose at the same time to discontinue the present process of filtration, it is doubtful whether in the end the consumer will be much benefited. It has been proposed more than once to tap one of the English lakes for the benefit of the water-consumers of London, but no practical scheme toward the realization of the project has as yet been brought forward.

Alcohol is again coming to the front as a factor in the causation of disease, and one worthy of serious attention. The Pathological Society has determined to set apart in the early part of next session three evenings for the discussion of the pathological changes produced by chronic alcoholism. Illustrative specimens will also be shown.

Our dental friends are evidently resolved not to be outdone by their medical brethren. A post-graduate course at the Dental Hospital of London is being arranged, and will commence in April next.

It is believed that a Royal Commission will shortly be appointed to inquire into the present state of higher education in London. If such prove to be the case, it is probably to this body that the question of medical degrees will be referred.

The drainage of the Brompton Hospital for Consumptives has been found to be very defective, and is being thoroughly overhauled. Some additions to the buildings are also being made.

SHALL A SURGICAL INVENTION BE PATENTED?

To the Editor of The Medical Record.

Sir: Permit me to propose a subject for discussion by the editorial staff of your estimable journal, or by any one of your readers who has an unbiassed judgment—if that is possible—to express upon the question, which is, the propriety of patenting surgical inventions.

That the writer's personality may contribute no bias to the discussion, please allow me to remain Dr. Incognito—one who has always been an obedient disciple under the code of ethics of the American Medical Association, but who, nevertheless, regrets the introduction into said code of the fourth paragraph as written under Article I., "Duties for the Support of Professional Character."

The paragraph mentioned is illogical, unreasonable, and unjust.

It is illogical because there is no parallel between a patent medicine and a surgical instrument. The one is a secret nostrum, very likely calculated to deceive, while the other bears on its face any worth it may possess. The paragraph is unreasonable and unjust because there is neither reason nor proof presented why a surgical invention should be so degraded.

"Equally derogatory to professional character is it," says the paragraph in question, that is, as reprehensible as any of the quackish procedures previously mentioned, "for a physician to hold a patent for any surgical instrument or medicine; or to dispense a secret nostrum, whether it be the composition or exclusive property of himself or of others. For if such nostrum be of real efficacy, any concealment regarding it is inconsistent with beneficence and professional liberality; and if mystery alone give it value and importance, such craft implies either disgraceful ignorance or fraudulent avarice."

It is very far from my intention to defend secret nostrums of any kind. What I do want to find out is, how came it that the whole medical profession was so duped by illogical legislation with reference to something that had no craft nor secrecy about it; but, on the other hand, must have manifest merit in it, or any legislation with regard to it would be undeniably useless? It is no wonder that such looseness has worked disruption and estrangement among medical men and organizations.

Perhaps you will say that the natural magnanimity of our medical fathers led them to allow this blunder to pass rather than to so publicly put themselves on record as maintaining any personal rights whatever of their own in the premises.

This is probably the best excuse that can be given for this hybrid paragraph. It is the one most likely to be given by the professors of surgery in certain medical colleges, who are extensively advertised by themselves and instrument-makers for the little changes they have added to this or that surgical instrument. Verily, they have their reward, whether they merited it or whether they "borrowed" the idea from some country doctor or hospital interne, who would either not see his advantage, or would naturally be discouraged about perfecting his invention.

Allow me, Mr. Editor, to propose a hypothetical question which I hope you will answer. It is a perfectly fair one.

Supposing a surgeon of inventive genius originates an improvement, or a new appliance in surgery, to perfect which extensive experimenting is required; to manufacture which, cheaply, dies and special machinery are imperatively necessary, and to introduce which into use requires considerable outlay in diagrams, printed explanations, etc., extensively distributed. If, under such circumstances, the inventor has confidence in the venture, should there be any odium attached to his protecting his discovery by letters patent? Will not the law of supply and demand settle the whole question, so that the mass of the medical profession will profit more by his discoveries than in any other way—namely, by the success of his improvements, their perfection, and cheapness? Is it not probable that the conclusion of such persistent labor would be more valuable, even if the results were expensive, than the dribbling way that many instrument-makers potter with half-completed inventions? Is it not also probable that the cost of manufacture by machinery would be so much less, under the protection of a patent, that the retail price would be less than when everybody tries to make it by hand? Then why not encourage invention among surgeons and allow them to protect themselves as other people do, instead of throwing all the profit into the hands of the instrument-makers?

Incognito.

January, 1888.

THE TREATMENT OF BOILS AND CARBUNCLES.

To the Editor of The Medical Record.

Sir: The editorial in your issue of February 25th, in which you called attention to the experience of M. Verneuil in regard to the treatment of carbuncle without incision, is of practical interest to all. As is well known, Sir James Paget, so long ago as 1869, in an article in *The Lancet*, condemned the treatment by incision, and I had supposed his methods were extensively followed. A method involving the same principles as those of M. Verneuil, but differing in detail, is one which I adopted several years ago, and have followed since, with much satisfaction. A man with a carbuncle on the back of the neck consulted me at my office, and as there were already some half-dozen small openings, it occurred to me to apply within the openings Battey's solution of iodified phenol, which was standing on my table for gynecological use. This solution consists of the scales of iodine one drachm, to carbolic acid crystals just liquefied by water, four drachms. I wound a probe with cotton, and, dipping it in the solution, thrust it in all directions into the openings, and, as well as I could, saturated the sloughing tissues with it. I gave the man tonics, and no opiate, and that night for the first time he slept; and a few days, with a couple more applications of the local treatment, sufficed for his recovery. Since that time I have used this treatment in several cases of carbuncle, and always with relief to the pain. The anæsthetic effect of the strong carbolic acid, and the caustic stimulant effect of the combination, seem to be just what is needed in this painful and indolent disease. I think I have sometimes aborted furunculi and hordeoli by applying this in the early stage to the apex of the swelling, and after a boil is opened, its application to the interior is useful. I usually give quinine in tonic doses, and sulphide of calcium, and I think that the suggestions of Sir James Paget, that, if able, it is well for patients with carbuncle to keep in the open air a part of each day, and to eat moderately of easily digested but nutritious food, are eminently wise.

Lawrence, Mass., February 27, 1888.

COLORADO AS A HEALTH RESORT.

To the Editor of The Medical Record.

Sir: In an October number of The Medical Record there appeared a paper read before the New York Academy of Medicine by Dr. Clinton Wagner, entitled "Colorado Springs and Davos-Platz compared as Winter Health Resorts." In his paper Dr. Wagner was so fair and lucid in description of this place and its chief features as a health resort that there remains little to be said. The discussion, however, following the reading of the paper brought out at least two points which I desire briefly to consider. First, Dr. Loomis casually alluded to the *aseptic* quality of the air of high altitudes. This special quality embraces a subject which I wish to more fully emphasize, and which I think has not heretofore been sufficiently appreciated by medical men, or received the attention its importance demands.

Years ago the hunters and trappers of this region noticed the fact that game killed and left upon the plains, and in the mountains, instead of soon undergoing decomposition, as is usual in lower altitudes, remained for a long time in a state of purity and freshness. Medical observers in this section have doubtless experienced but little difficulty in the treatment of their strumous patients, and have noticed the rapidity with which such cases are restored to health. Old cases of scrofula involving indurated and suppurative glands, cases showing markedly the cachectic appearances of blood-impoverishment, as a rule recover perfect health here with the aid of little if any medication. Chronic cases of syphilis in the secondary or tertiary form in the large majority of cases are frequently restored to health by virtue of the antiseptic nature of the atmosphere. The stimulating effect of the air aids in throwing off old accumulations, diseased tissues assume new life from the impetus derived from a purer quality of blood, the rarefied air acting as tonic, alterative, and antiseptic. Most cases of phthisis defer change of residence to climatic resorts until the disease is so far advanced that when they reach such resorts their condition is one of general enfeeblement, and we find them suffering with torpid functions and poverty of blood. Softening and suppurative changes are in progress, and there is loss of tone and vitality. Such cases recover health in high altitudes, the aseptic air bathing, as Dr. Loomis suggests, the diseased surfaces and causing arrest of unhealthy processes, and also causing reparative changes to more rapidly occur. In the antiseptic quality of mountain air there is an important curative factor in the treatment of numerous chronic diseases, and that the subject will enlist the attention its importance demands there is no question of doubt.

The second point alluded to in the discussion of Dr. Wagner's paper was also by Dr. Loomis, who thought that phthisical patients who recovered health here would find it necessary to remain in the climate two or three years after recovery was established, and also that the *permanent* cases of recovery were not so great in number as those cases recovering in lower altitudes and in warmer climates.

It is quite true that many cases coming here with extensive area of lung-tissue involved, softening and breaking down, find it necessary to remain several years after recovery has taken place. The majority of such cases, usually considered hopeless, are, after the ravages of the disease have become arrested and recovery has been assured, left with delicate constitutions and enfeebled vitality, subjecting them to greater susceptibility to changes of atmospheric temperature, and are, as a consequence, in no condition, if even so inclined or advised, to take the risks of a permanent residence in a less dry and sunshiny climate. Such classes of cases are advised to remain here until all diseased processes are not only healed, but until there occur strength and elasticity of tissue and a complete gain in the general condition. Unfortunately, most patients leave before these results have been attained. They grow better, become impatient to return home and to business, are not fully recovered when they leave, and hence in a few months are compelled to return and go again over the same ground. As a rule, individual results depend to a great extent upon individual temperament, and hence it is impossible to correctly say just what effects will be, or how long cases will be compelled to remain before recovery takes place. In looking over my book of recorded examinations of phthisical cases, I find it contains many cases who recovered health here, and who are now living and pursuing their former vocations in the East.

One case I notice which, I think, would alone entitle this climate to consideration as a means of effecting permanent cure. The case is that of an actor who came to Colorado in September, 1884. His disease was catarrhal phthisis, involving the upper third of the left lung. His general condition was feeble. Weight, one hundred and twenty pounds. Evening temperature, 103°; profuse night-sweats, loss of appetite, racking cough, and insomnia. This patient remained here one year, and then returned to New York and his profession. His weight was one hundred and sixty-five pounds, and his general health excellent. The lung was perfectly clear, respiratory murmur normal, and diseased lung fully restored to healthy function. This gentleman, whose profession has taken him to every portion of the United States, since leaving here, has continued in perfect health, and in a letter received from him two weeks since he informs me that he has had no return of his former trouble, that his general health is excellent, and his weight, at the date of writing, was one hundred and seventy pounds.

Another case demonstrating the permanent curative effect of this climate which I recall is that of a young lady whose residence is Norwalk, Conn. She came here in 1877, had been an invalid for four or five years, was a fair, fragile girl, and had tried Nassau and Florida without effect, and ventured to Colorado with but little hope of benefit. Examination revealed right upper third involved; caseous infiltration and tubercular deposit, summit and infra-clavicular space, left lung. This patient remained here until spring of 1882, since which time she has resided in the East, and in the enjoyment of perfect health.

If, within the limits of this article, I could describe in detail the histories of many cases who fully recovered health here and are now living in different portions of the United States! I am fully aware that every health resort has its enthusiastic admirers and defenders, and many have advantages, while none are perfect in each and every particular. There are cases coming each year to this climate who would in all probability receive more benefit somewhere else, and the conscientious physician of this region frequently advises patients to seek a more suitable climate. I wish, however, to be understood that those cases recovering here derive more permanent effect, and good results continue longer, than obtains in any other region on the globe. When we consider the vital properties of the air, its aseptic qualities causing the disappearance of blood-impurities and the repair of diseased tissues; its stimulating qualities relieving sluggish circulation, and causing torpid accumulations to be thrown off; its electrical properties in such diffusible state as to make up the best tonic that could be prescribed for enfeebled constitutions; and, added to all these, the greater number of sunshiny days, which invite the morbid invalid out-of-doors, enabling him to regulate his exercise, so essential to producing solid tissue and strength of body—an air entirely free from malaria, fog, and the usual dampness found in warmer and lower elevations during the winter months. With such elements of climate, and the abundant experience of many cases of recovery who are living in Eastern homes, there can be but little question that the *permanency* of the cures are established facts, and that such a climate cannot be judged adversely as regards its curative properties.

B. P. ANDERSON, M.D.,
Ex-President Colorado State Medical Society.

COLORADO SPRINGS, COL., February 20, 1888.

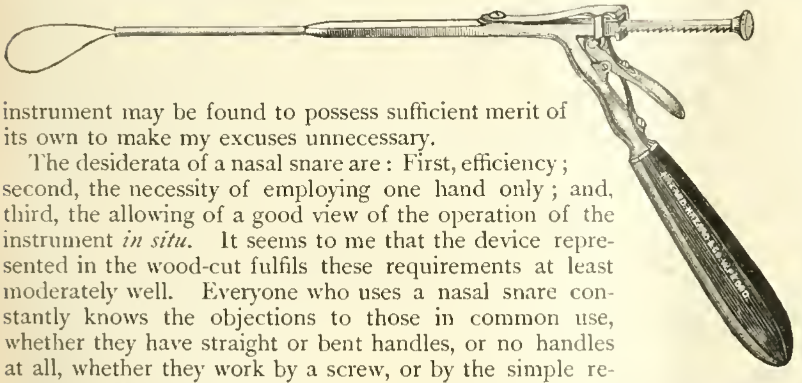
New Instruments.

A MODIFIED NASAL SNARE.

By JONATHAN WRIGHT, M.D.,

LARYNGOLOGIST TO THE ROOSEVELT AND DEMILT DISPENSARIES, NEW YORK.

IN presenting a new nasal and laryngeal instrument, or, rather, a new modification of an old one, I feel that I owe an apology to the medical public. So many excellent nasal snares already exist that it may seem superfluous to add another to the list. However this may be, I hope the instrument may be found to possess sufficient merit of its own to make my excuses unnecessary.



The desiderata of a nasal snare are: First, efficiency; second, the necessity of employing one hand only; and, third, the allowing of a good view of the operation of the instrument *in situ*. It seems to me that the device represented in the wood-cut fulfils these requirements at least moderately well. Everyone who uses a nasal snare constantly knows the objections to those in common use, whether they have straight or bent handles, or no handles at all, whether they work by a screw, or by the simple retracting power of the fingers.

The instrument represented here was recently made for me by the surgical department of Hazard, Hazard & Co., and I am indebted to them for several valuable suggestions as well as for obliging services.

It consists of the cannula and stilette of a Sojou's snare to which a handle with a lever of the first kind has been adapted. The stilette is screwed into a small straight bar, on the under surface of which is a set of cogs in which works a small tongue propelled by the short arm of the lever. Pressure of the thumb of the hand grasping the handle upon the long arm draws the stilette through the cannula and tightens the wire loop at the end. Both the long arm of the lever and the little tongue on the short arm are provided with springs which throw them into a new position when the pressure of the thumb is removed. A spring on the top of the sheath in which works the cogged bar catches the latter below as it is drawn out, and prevents it from slipping forward.

When the operator desires it, pressure on this spring with the index-finger of the employed hand releases the cogs, and with the thumb the bar, with stilette and loop, can be pushed forward to the original position.

The lever can be worked so rapidly as to almost immediately cut through the tissues, or as slowly as desirable. The power attained, depending as it does on the length of the long arm of the lever, is great enough to break the strongest No. 5 piano-wire. For a laryngeal or post-nasal attachment, all that is necessary is to unscrew the cannula and stilette at the point marked in the wood-cut by the beginning of rectangular sheath and replace them by a bent cannula and a flexible stilette. The handle also unscrews, so that the instrument may be packed in a small compass. The cogged bar may also be withdrawn, and this allows of the instrument being quickly and thoroughly cleaned.

Those not liking Sojou's method of securing the wire loop can easily adapt a clamp for the wire to the cogged bar and dispense with the stilette.

I can only say, in conclusion, that in my work at the Roosevelt and Demilt Dispensaries I have found that it removes some of the difficulties of intranasal surgery. It seems to do all that a snare can do, and its preparation for use is the work of a moment. The same wire can be repeatedly used if wished.

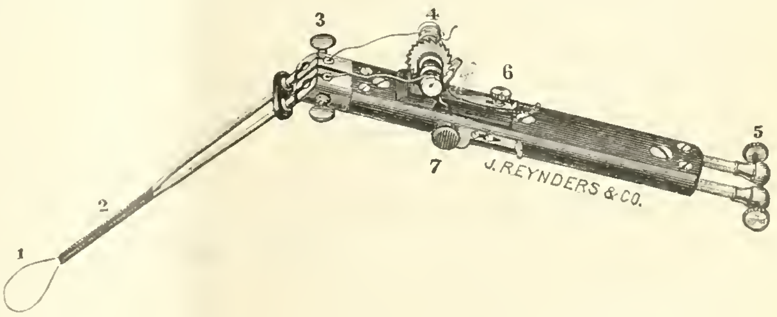
73 REMSEN STREET, BROOKLYN.

A NEW CAUTERY-SNARE FOR REMOVAL OF POSTERIOR HYPERTROPHIES OF THE TURBINATED BONES.

By J. W. GLEITSMANN, M.D.,

NEW YORK.

THE instrument to be described is constructed on the principle of Jarvis' snare, and is intended to shorten the length of time consumed in the operation and to guard against possible subsequent hemorrhage. Very slow traction is recommended by the originator of the cold snare himself, and practised by all operators, but, nevertheless, two cases of very annoying hemorrhage occurred to the writer in spite of faithful observance of all precautions. The desire to overcome these two disadvantages led to the construction of the following cautery-snare:



1, Loop; 2, draw-tubes; 3, set screw for draw-tubes; 4, windlass; 5, binding posts; 6, movable spring-catch to secure windlass; 7, current-interrupter.

The handle is the usual universal handle used with Fleming's cautery-battery. The windlass secured by the spring-catch holds the wire in position, and allows of tightening the wire, thereby answering the same purpose as the small screw in Jarvis' snare. To obtain the spring and elasticity of the cold wire, a composition of platinum and iridium was devised which offers the same resiliency as the ordinary steel wire, and retains the same outward turn of the loop necessary for engaging the posterior hypertrophy. While the platinum wire bends at each obstacle, the platinum iridium snare resumes its original form and curve as soon as it leaves the nares and enters the naso-pharyngeal cavity. It does not require more heat than platinum, and when the hypertrophy is once caught the operation can be finished without delay. The removal of the redundant tissue by heat guards against bleeding, and the whole procedure is considerably less distressing to the patient on account of its shorter duration. Among several operations, this fact was most exemplarily demonstrated in a patient from whom one hypertrophy was removed with the cold, the other with the cautery-snare, and who could not express sufficient gratification in comparing the two methods.

The combination of platinum and iridium can also be used in other instances with advantage, where it is thought advisable to press the loop firmly against the tissue; f. i., anterior nasal hypertrophy, nasal polypi, etc. When the dense longitudinal granulations of so-called lateral pharyngitis, in the neighborhood and behind the posterior palatine pillar, are to be removed by the cautery, a loop formed of heavy platinum-iridium wire, and large enough to encircle the patch of granular tissue, can be used. The wire, being elastic, will remain *in situ* by a slight pressure. After destroying the tissue to a certain depth the current is interrupted, and subsequently the granulations slough away.

117 SECOND AVENUE.

LEVELLED ABDUCTING PRISMS.

BY WILLIAM H. WILMER, M.D.,

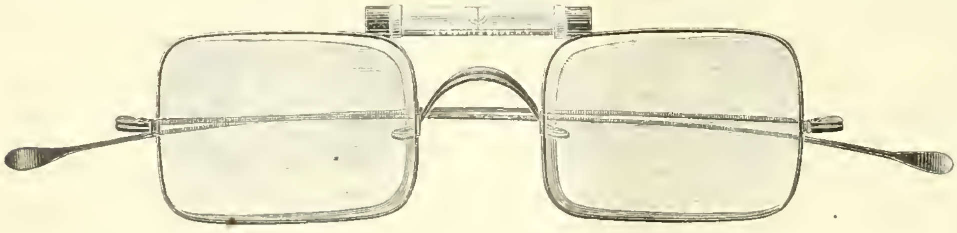
ASSISTANT TO THE CHAIR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC, AND VISITING PHYSICIAN TO THE OUT-DOOR DEPARTMENT OF BELLEVUE HOSPITAL (DISEASES OF EYE AND EAR), NEW YORK.

AT the present day many neurotic conditions are attributed to a want of equilibrium in the ocular muscles, especially to slight dynamic differences in the superior and inferior recti.

The methods, however, that are generally employed for detecting *slight* degrees of insufficiency of these muscles are certainly not reliable; for, with ordinary abducting prisms, vertical diplopia may be produced by inclinations of the head too slight to be noticed by either the physician or the patient.

In making our examinations together, Dr. Gruening and myself were never sure that our prisms were placed with absolute correctness; and, to our queries regarding the supposed position of the head, the patients invariably replied that they could not judge whether the head was held exactly straight or not. It will readily be understood that any asymmetry of the brows, or other landmarks of the face, presents another source of perplexity to the observer.

To meet this difficulty, the simple device of having a delicate level placed upon the prisms, as in accompanying cut, was resorted to by the writer, and this little contrivance has now been used in a number of cases with satisfaction.



The illustration represents abducting prisms of eight degrees each, set in an immovable frame, and surmounted by a spirit-level marked to indicate its centre. The glasses are made by Meyrowitz Bros., New York.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 10, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	3	2
Scarlet fever	159	17
Cerebro-spinal meningitis	7	6
Measles	69	5
Diphtheria	144	40
Small-pox	16	1
Yellow fever	0	0
Cholera	0	0

THE HUMAN BREATH A POISON.—At a recent meeting of the Académie des Sciences, Professor Brown-Séquard referred to some experiments he had conducted with a view to determine what, if any, were the toxic effects of the human breath. In condensing the watery vapor coming from the human lungs he obtained a poisonous liquid capable of producing almost immediate death. This poison is *an alkaloid* (organic) *and not a microbe* or series of microbes, as might have been imagined. He injected this liquid under the skin of a rabbit, and the effect was speedily mortal. The animal died without convulsions; the heart and large vessels were engorged with reddish blood, contrary to what is observed after ordinary death, when the quantity of blood is moderate and of a dark color. In conclusion, this eminent physiologist said that it was fully proved that respired air contained a volatile toxic principle far more dangerous than the carbonic acid which was also one of its constituents, and that the human breath, as well as that of animals, contained a highly poisonous agent.—*The Medical Press*, February 1, 1888.

SPASMODIC RIGIDITY OF THE OS.—This is really a state of tetanus in the anterior lip of the uterus, according to Doléris, found usually in neurotic primiparæ when premature rupture of the membranes has allowed the waters to entirely escape. The suffering is, of course, intense, and the patient's state of mind pitiable. Under chloroform the condition disappears at once, and labor, as a rule, progresses favorably. Dr. Doléris utters a protest against antispasmodics of all kinds in this complication, and against the classic views upon the subject of spasmodic rigidity that are found in books.—*Post-Graduate.*

CHOLERA INFANTUM AND THE WEATHER.[1]

BY A. SEIBERT, M.D.,

NEW YORK.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY: It almost appears superfluous to read a paper on so well known a subject as the relations between acute gastro-intestinal disturbances of infancy and the weather. It almost sounds like asking a fellow-sufferer in mid-summer, and the thermometer in the nineties: "Is it hot enough for you, old boy?" But if one will but take the trouble to collect some of the opinions regarding this subject, he will be astonished to find quite a variety of them, proving that as yet definite knowledge has not been arrived at.

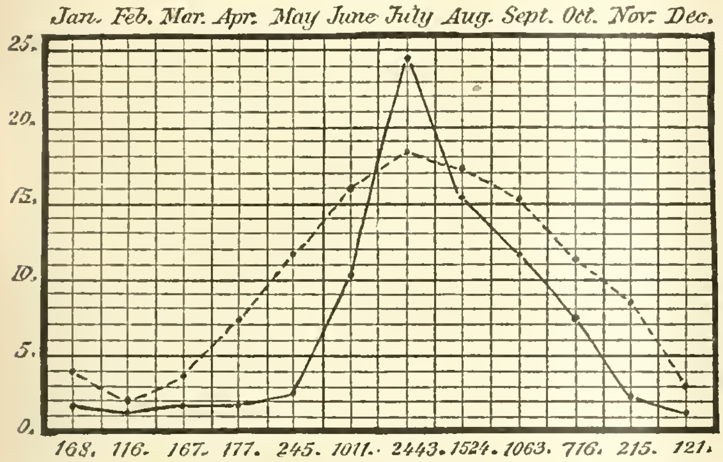

CHART I.—Morbidity of Cholera Infantum. German Dispensary: 8,036 cases, and average monthly temperature.

Curious to gain some real facts, based upon figures, regarding this question, I gathered all cases of acute gastro-intestinal catarrh, in children under five years of age, treated during the time of my service in the children's department of the German Dispensary, a period of ten years. These cases I arranged according to date, and then compared their frequency with the exact meteorological phenomena of every day, during these ten years. In this investigation I have been guided by the experience gained in my examinations regarding the weather and fibrinous pneumonia, published in the *American Journal of the Medical Sciences*, January, 1882, the *Berlin Klin. Wochenschrift*, Nos. 18 and 19, 1884, and No. 17 of 1886.

From January 1, 1878, to January 1, 1888, the total number of cases of acute gastro-intestinal catarrh in our department, occurring in children under five years of age, was 8,036.

Arranging our cases according to the different months of the year in which they appeared, and adding up their sums (as the ten January months, ten February months, etc.), we gain the black line on Chart I., demonstrating that November, December, January, February, March, and April show very few cases; that May is a little more inclined that way; but that during June, July, August, September and October this disease is very frequently met with; and the difference between the two halves of the year is so marked and great, that the term "summer-complaint" seems very appropriate. This difference at once suggests that potent agents must prevail during the warmer months of each year, aiding the development of this malady. Adding up the temperature means of the different months, we get the red line on Chart I., showing that the highest temperature is found when the greatest number of cases appear (the ten July months with 2,443 cases), and the smallest number during the coldest weather (116 cases during the ten February months).

Having gained this result, we might stop, feel entirely satisfied, and live on under the impression that statistics have verified our supposition, that heat will produce this trouble; but, as I pointed out years ago, that monthly averages are simply guides to the truth in statistics of this kind, and that they are absolutely unreliable as conclusive evidence, it certainly would not behoove me to stop here. On again looking at our chart, we notice (1) that our disease is found all the year around, not frequently in January and February, it is true, but the fact remains that it does appear during the coldest weather; (2) we notice a decided difference in the morbidity- and temperature-lines; they have the same direction, but do not run parallel to each other. For instance, the greatest difference exists in morbidity between June and July, while the difference of temperature is not near as great as between May and June; the August months, with but 1,524 cases, show a morbidity less than one-third of that of the July months; while the corresponding red line shows the difference of temperature to be but a small one. We notice the same, the very same phenomenon on Chart II., showing the mortality from diarrhœal diseases of the ten years in this city, of children under five years of age, compared with the mean temperature. The same enormous difference between the Junes (with but 4,103 deaths) and the Julys (with 12,468 deaths); while the August months

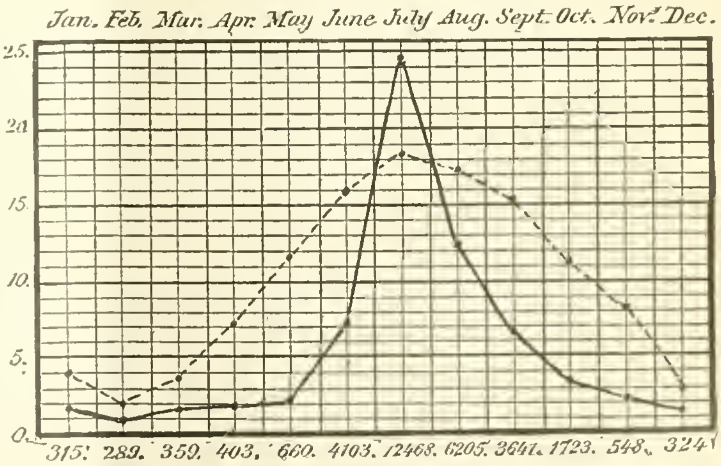

CHART II.—Mortality of Diarrhœal Diseases in Children under Five Years of Age. New York City: 31,048 cases, and average monthly temperature.

---

[1] Read at the Stated Meeting of the New York Academy of Medicine, February 16, 1888.

show exactly one-half as large a mortality as the Julys—namely, 6,205 deaths. These two charts, which look alike enough to be twins, demonstrate, first, that in the long run, with a large material, mortality and morbidity must show proportionate figures, and must and will sustain each other as correct; second, that children not alone get sick from cholera infantum all the year round, but that the proportion of deaths is exactly the same in winter as in summer—during the hottest as well as during the coldest weather! So no doubt we are not yet at the bottom of this question concerning the temperature. Some other facts will show that still more.

In July, 1881, the mean temperature was 80° F., that of August 82°, and that of September 81°; yet we have 290 cases in July, 223 cases in August, and 137 in September. And in July, 1884, we notice 75.6° F. as the mean, and in August and September, each, 76.7° F.; yet July has 266, August has 156, and September has 164 cases; while the mortality of both July months was nearly double that of the August, and three times as large as in the two September months!

The mystery becomes more obscure when we figure out the mean temperature of the six summer months of each year, and compare these figures with the morbidity-line. We notice (on Chart III.) no similarity whatsoever, demonstrating the fact that one summer (as, for instance, 1880) may be decidedly warmer than another (as 1879 or 1884), and yet will bring forth less summer-complaint.

The same result we obtain after comparing months instead of years; for instance, the ten July months (on Chart IV.). Here we notice also no similarity in the running of the temperature and morbidity, both being apparently independent of each other; showing that one July may be hot and have many cases (as in 1879), and the next may be exactly as warm and have less than half the number of cases (as July, 1880). The same result we have on comparing all the other months. Only one point appears peculiar upon comparing the temperature of the May months, that whenever the mean temperature is below 58° F., the amount of cases is no larger than during an average cold winter month—a fact I wish you to keep in mind till later.

Now, then, we have found so far that, though the temperature evidently has some decided relation to the frequency of cholera infantum, yet we have no right to accept our first impression, that the higher the more, and the lower the temperature the less, frequent do we find this complaint; on the contrary, we must admit that "comparison of monthly means of temperature during the summer months shows that the frequency of summer-complaint (like its mortality) is independent of the rise and fall of atmospheric temperature."

Before finishing the question of temperature, we will look up other factors of the weather. Suffice it to say, that a careful comparison of the barometric figures of the warmer months failed to give even the slightest evidence of influence, as we have many and few cases during high as well as during low pressure, compared as to months as well as to daily ranging.

On Chart IV. we can compare the average humidity of the ten July months with the temperature- and the morbidity-line, showing that a hot and dry July (like that of 1879) and hot and medium moist atmosphere (as in July, 1882) may bring forth very large numbers of cases (299 and 303, in our collection the two largest); while still hotter atmosphere, impregnated by large quantities of moisture (as in July, 1885 and 1887, the hottest and muggiest months of our collection), shows but a medium number of cases (232 and 196, respectively). I have carefully selected all moist-warm and all dry-warm days of the ten summers, and compared their position with our morbidity-lines, and I have failed to find even the slightest trace of influence. For the monthly sums of mortality this statement also holds good. I can further report that, though the ten August and ten September months (with three exceptions of each) show by far a greater amount of moisture than the Julys, yet their inclination to the production of this disease is by far less. So we may lay the popular opinion at rest that warm-moist weather predisposes more to the causation of summer-complaint than warm-dry atmosphere.

The rainfall necessarily appeared to me a meteorological factor of great interest. Through the kindness of Chief Engineer Birdsall, of the Croton Water Works, I was enabled to get exact figures on the water-supply of this city, including the amount of water used daily, the varying depth of Croton Lake, the rainfall in this and other lakes in Putnam County occasionally used as storage-lakes, the number of days in the different months when the storage-supplies (from the upper lakes) were drawn upon (as their water is not so clean as that of Croton), and the amounts of these drafts. All these figures I carefully compared with our figures and also the mortality figures of the Health Department, according to years, months separate and collected, and many an hour of the night did I spend on this part of the investigation; but my results were absolutely negative, I am sorry to say—all the more sorry because it had been a pet idea of mine to believe that want of water in the upper stories of our tenements lent conspicuous aid in the causation of summer-complaint. As an example, you can see on Chart V. the amount of rain (by inches) of each of the August months, together with the temperature-line, which is quite even. In August, 1878, and August, 1884, both temperature and large amounts of rain are even, yet the morbidity differs like 2 to 3, 99 cases for 1878 and 156 for 1884. Again, August, 1880, had four and one-half inches of rainfall, August, 1882, but one and one-half inch, the temperature being the same, and the morbidity-figures vary but little, 146 to 164. The same result in 1885 and 1886. Again, we must admit that the local rainfall does not influence the prevalence of cholera infantum.

The velocity of the air-current shows no effect upon our morbidity-figures.

At this point of our investigation you may fittingly quote Goethe's "Faust:" "I know as much as I knew before;" but you will pardon me for having taken you over these lost battle-fields of figures, where the figures got the best of me, for it is essential to the understanding of the second half of our work. Six years ago I first pointed out the necessity of careful detail-work for investigations of this kind, and demonstrated the doubtful value of monthly means, averages, and sums. Time does not permit me to discuss this point over again. You will be satisfied to know that my former arguments and methods have been universally accepted since then as conclusive and correct. So now we will return to the temperature and go into detail.

As yet it is a point for discussion whether atmospheric heat is capable of directly affecting an infant's body in such a way as to produce cholera infantum. Those believing in this theory speak of reflex action from the peripheric nerves to the nerve-centres, and from there to the alimentary canal; others seem to regard the cooling-off of the child's body in hot weather as the agent bringing about, or aiding to bring about, gastro-intestinal troubles, and therefore believe in protecting the stomachs of infants with flannel bandages as a prophylactic measure of importance. To find what statistical truth there was in these theories I collected all hot days of the ten summers, days where the temperature reached 85° F. and above. Evidently, those months showing the most of these hot days ought to show the greater number of cases, and *vice versa*, and those days ought to be followed by the greater number of cases—in case these theories were founded on facts.

On comparing the ten July months on Chart VI., we find no evidence supporting these views. July, 1887, had eighteen days with the temperature mounting to 85° F. and above, twelve of this number going into the nineties; yet the number of cases treated was far below the average and one-third less than July, 1882, where only fifteen hot days were noted, and showing the greatest number of cases—303. July, 1878, with fourteen hot days only, had 99 cases, while July, 1884, with only four hot days, had 266! Neither did I find a greater mortality in those months having the greater number of hot days.

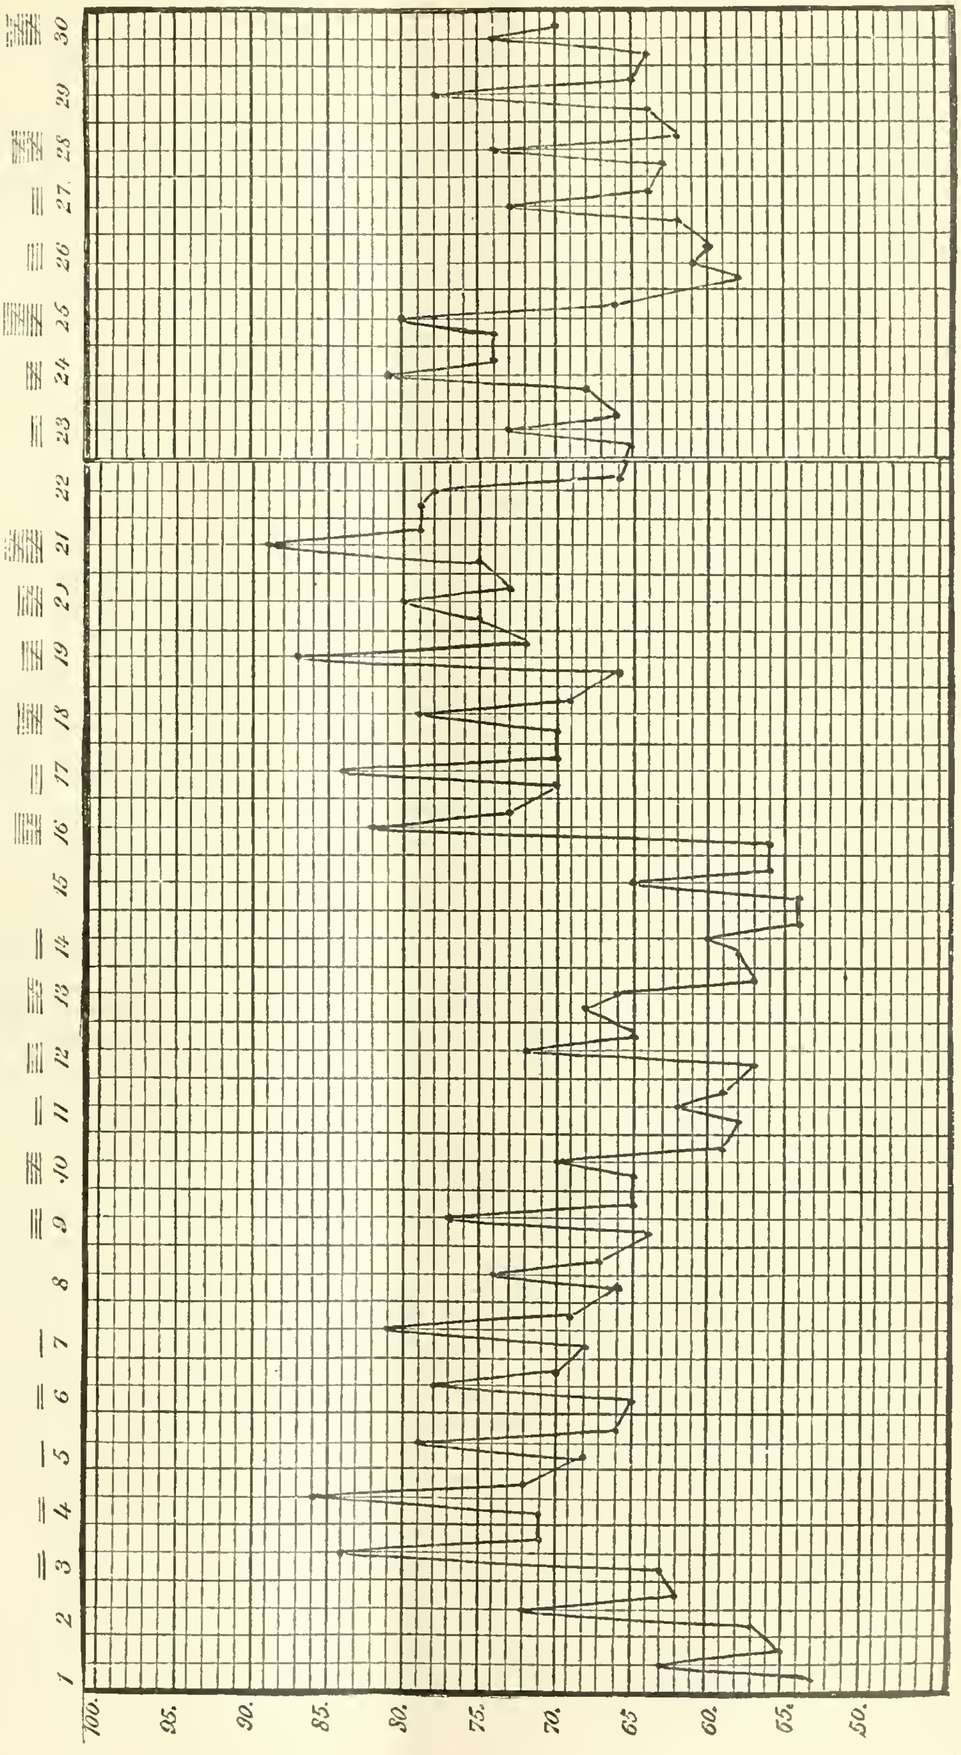

CHART X.—June, 1884.

On Charts VII. and VIII. (showing the maximum and minimum temperature of each day of the respective months, together with the number of cases overhead), we can study these circumstances in detail.[1] In June, 1880, we notice the temperature rising often above 80°, especially during the latter half of the month; while in the latter half of June, 1887, the temperature seldom goes above 80°, and yet we have the same number of cases in the last two weeks of both months. On Chart VIII. we notice in July, 1887, the maximum temperature constantly nearer to 85°, and very often above this line, the minimum temperature being constantly much higher than that of July, 1881, whose maximum temperature only reached 90° on one day and passed 85° on only three more; and yet we notice that the cooler month has 290 cases and the by far hotter one only 196, a proportion of 3 to 2! But the most striking example is July, 1884, during which time the temperature never reached 90°, passed 85° but on three days, and altogether reached 80° but on eight days, showing a remarkably cool summer month, and yet we have 266 cases of summer-complaint; while the following August had sixteen days where the temperature reached 80°, four days with 85°, and one with 90°, and yet the number of cases is but 156, one-third less than in the preceding decidedly cooler July! The mortality stands 1,109 for July and 633 for August, a bit over one-half. I might keep on for hours and give you any quantity of evidence that very high temperatures do not favor the production of cholera infantum more than medium warm weather. This July of 1884 is a month showing peculiar healthy weather, as we would call it: Humidity very variable, changing markedly three times a day, cloudy rainy days changing with bright sky, refreshing westerly air-currents, and yet so many cases of illness and so many deaths. How, then, do we account for the phenomenon that the warm months show such a decided preference for this disease? Well, we are now convinced that *hot* weather is not necessary—we have buried another favorite idea long fostered in our bosoms, so let it rest, and turn to its relative, *warm* weather.

---

[1] The charts alluded to were all demonstrated, the larger ones showing all the weather-constituents of each day.

You will notice on the large charts that I have drawn a lower heavy line near the temperature and humidity line; it points out the place for 60° F. Now, by glancing over all these charts, watching the relation between the red temperature-line, and especially its lower points (denoting the minimum temperature of each day), you at once perceive that as soon as the minimum daily temperature reaches about 60° F. and above, and stays so for a few days, we notice more than the usual number of cases of gastro-intestinal catarrh (as May 19th, 20th, 21st, and 27th, and June 3d to 7th). If the minimum temperature remains above 60° F. for a longer period, say one week or more, then we notice cholera infantum becoming epidemic—no matter if the maximum temperature goes into the nineties or remains below 85° or even 80° F. The same law we find in October, the month of departure for summer-complaint. On the 2d and 3d the temperature goes down to 55° F., but for the next five days never below 60° F., showing an elegant exhibition of epidemic summer-complaint; again, on the 9th and 10th the minimum temperature is below 60° F., resulting in four meagre days, the 10th, 11th, 12th, and 13th; and the 20th to the 23d, with higher minimal temperatures, result in two corresponding attempts to keep up the high morbidity; then the air cools off for good, and cholera infantum only appears in sporadic manner, but even then more often after a warm night.

As you here see these large charts, so I have examined every summer month of these ten years, and every batch of days in them, and you will have to take my word for it that in every instance this law, or rule, is found to exist.

So we can make the statement:

1. Hot weather (either dry or moist) is not necessary for the epidemic appearance of summer-complaint.

2. Warm weather (either dry or moist) showing minimum daily temperatures of not less than 60° F., brings on the epidemic appearance of cholera infantum invariably in every year, irrespective of the height of the maximal daily temperature, as in the latter part of June of nearly every year.

3. Summer-complaint loses its epidemic character as soon as the minimal daily temperature remains below 60° F., as in the latter half of October of nearly every year.

4. Therefore, this disease cannot be brought about by the direct working of high temperatures on the infantile body, but must have other causes.

What may these causes be? Let me suggest one of them. The lowest temperature of each day in summer is at night; the milk feeding our children is brought to the city during the night, shaken and jolted in cars and wagons, absorbing impurities from the time it leaves the cow until it enters the mouth of the child; thus, the conditions for decomposition are given, in every instance, without exception. The only question remaining is: How far is your New York City milk advanced in decomposition when you get it? Now, we know that low temperature retards putrefaction and decomposition of any animal or vegetable substance, and that higher temperature aids it, and especially milk. Now, Dr. Cyrus Edson sent me a letter two days ago, in which he states (in answer to a written request of mine) that, according to his experience and that of others, milk will begin to turn readily at 60° F. and over. Chief Engineer Birdsall made the statement that as soon as the temperature of the water in Croton Lake reaches 60° F. and above, it has a peculiar taste, due, no doubt, to decomposed material in it, or development of organisms of decomposition. My only explanation for the so much higher morbidity and mortality of July over August is, that it takes a few weeks of high morbidity and mortality every year to fully arouse the public, and especially the poorer classes, to the dangers threatening their children, and to impress upon the parents' minds the very simplest fundamental principles of how to avoid them—a beginning of which was made by the distribution of the rules of how to handle milk and babies, written by the President of this Academy about fifteen years ago.

I have promised our President not to speak about teething, and so I will stop, thanking you for your kind attention, and especially thanking Dr. Nagle and Dr. Cyrus Edson of the Board of Health, Chief Engineer Birdsall, Department of Public Works, and Sergeant Dunn, of the Signal Service Office, for the kind aid they all gave me in this work.

122 East Seventeenth Street.

SOME POINTS IN THE TREATMENT OF CHRONIC ALBUMINURIA, OR BRIGHT'S DISEASE.[1]

By CHARLES S. WOOD, M.D.,

NEW YORK

In speaking of the above-mentioned disease, I do not propose to dwell upon its etiology, only mentioning the more generally recognized causes of the same, as they are so numerous that their mere recital would occupy the time allotted to this paper.

Formerly, the chief causes of this disease were supposed to be inflammation or congestion of the kidneys, or both combined—such as the congestion accompanying pregnancy, from the pressure of the child upon the uterus, thereby preventing the flow of urine from these organs to the bladder; the exanthemata, in which the acute form is so often seen; a rigor following a sudden suppression of the excretions of the skin; the abuse of alcohol, etc. But undoubtedly much the most potent cause, and the one which must be constantly borne in mind in the successful treatment of the disease, is degenerative changes occurring in the different organs and tissues of the body as a result of hereditary tendencies, as well as of climatic and telluric influences. A notable effect of the latter may be observed in the condition of the atmosphere and its surroundings generally recognized as malaria, which is by many good observers believed to be provocative of the disease under consideration to a greater extent than any other one cause. I think it is a common observation by physicians that in localities where ague is frequent among the people there is to be found the greatest number of cases of Bright's disease. That during and subsequent to the chill, albumen in the urine is frequent, but soon passes off as the chill and fever are controlled by appropriate treatment. That when we get a condition, so often seen, of chronic malarial poisoning where distinct exacerbations do not occur, yet where there is a marked anæmia with poor appetite, sluggish bowels, torpid liver, or even enlarged with the spleen, with all the secretions depraved, physical and mental hebetude, etc., then a condition exists directly tending to convert a temporary acute albuminuria into the chronic form, so difficult to treat and so fatal in its results. This cause should, it seems to me, be constantly borne in mind, as an important guide in the way of treatment.

I will quote a few authorities, among the large number available, who are strong believers in the doctrine of the malarial origin of the disease, or at least of its being one of the most important factors in its production.

Blackhall, in 1818, believed nephritis and albuminuria to be frequently caused by intermittent fever, and described the disease as having immediately followed such attacks.

Chenoriard, in the Department of the Loire, France, in

---

[1] A paper read at a meeting of the Northwestern Medical and Surgical Society of the City of New York, February 23, 1888.

1845, expressed the opinion that intermittent fever, so common in that locality, was one of the principal causes of nephritis and albuminuria.

Neret, also of France, described many such cases in 1847, and declared that one-fourth of all cases of intermittent fever either had at the time, or were followed by albuminuria. Lenz, in his inaugural address, claims that intermittent fever was a frequent cause of nephritis, and of the chronic form of which we are speaking. Rosenstein, in 1870, saw in Dantzic, on the Baltic Sea, two hundred and thirty-nine cases definitely attributable to malaria. Bartels, in his clinical lectures, says, while admitting that he had not been able to trace the granular, contracting kidney to malaria, that chronic inflammatory enlargement of the kidney may, in isolated cases, from acute nephritis following a severe chill or scarlet fever, pass into that variety, but that malaria was the most frequent of the well-established causes of this disease. Hertz asserts that it is no uncommon thing to find albumen present in considerable quantities, in intermittent fever. Atkinson, of Maryland, says albumen is to be found in the urine either only on the fever days or during the intermission as well, and disappears on recovery. Still, cases frequently occur which pass into a chronic diffuse nephritis. Soldaton, of the Russian army, detected derangements of the kidney in three hundred and fifty soldiers of the Russian army in cases of autopsy, dead of malaria in East Roumelia during the summer of 1878. Dickinson, while denying malaria the first place in its etiology, admits that he had seen several instances of persistent albuminuria and symptoms of the granular kidney in persons recently returned from India, who, while there, suffered severely from malarial fever. McLean says: "I can confirm, from personal observation, Dr. Parke's remark that chronic Bright's disease is a consequence of malaria. Many old Indians who have suffered from malarial fever die of this disease." Woodward, of our own army, says of the results of chronic malarial poisoning: "Disorder of the kidneys frequently complicates the condition under consideration. Scanty, more or less albuminous urine is often observed, and those cases which occasionally perish with the symptoms of acute uremic toxæmia not infrequently terminate in chronic Bright's disease, with confirmed albuminuria, œdema, or general anasarca and the whole train of the symptoms of that disorder." Busey reports a number of cases of renal disease in children, the origin of which he attributes to malaria. Dacosta states that he has seen a large number of cases of Bright's disease following malaria. Observations upon renal alterations due to malaria have been made by Loring, Pepper, Clemens, and others.

PATHOLOGICAL ANATOMY.—For all practical purposes it is only necessary to note the two more commonly recognized morbid conditions of the kidneys, viz., the large, white, swollen appearance of the organ and the contracted, granular, or fibroid. The former is believed to be largely due to malarial poisoning; the latter to chronic degenerative changes, taking place not alone in the kidneys but in the different organs of the body. The former, constituting the diffuse tubal variety, may lead, and often does (unless proper therapeutic measures are adopted), after a greater or less lapse of time to the second or granular form and thereby become exceedingly intractable. Rosenstein remarks that, although cases usually get well or die before granular kidney develops, there can be no doubt that this form of kidney may result from malarial poisoning. Admitting the fact that, with the greatly improved methods of analyzing the urine, both chemically and microscopically, which we now possess, not only albumen but hyaline and granular casts are found in the urine in very many diseases, such as the exanthemata, rheumatism, pneumonia, the various forms of continuous fever, etc., as well as in apparent health as after violent exercise, sea-bathing, severe mental emotions, after eating certain kinds of foods, as tapioca, or eggs in large quantities, in epilepsy or the eclampsia of children, and as a rule that these temporary conditions are not dangerous, seldom requiring treatment; still, the form under consideration, depending largely upon malaria, should never be neglected, as I am convinced, from many years' observation, that the tendency is for the disease to pass into the granular or cirrhotic stage. True, the transitory attacks of malarial albuminuria, like those from other causes, usually recover of themselves, for the reason that the symptom is due to the visceral hyperæmia alone, and disappears on the subsidence of this. Its persistence is the only alarming feature. Alexander Rey studied the pathological anatomy of renal alterations of malarial origin; the kidneys examined by him owed their changes to intermittent fever. Soldaton observed in kidneys, after remittent fever, enlargement sometimes reaching twice their normal size. Having briefly glanced at the etiology and pathology of Bright's disease of the kidneys, I will claim your attention for a few minutes to some points in the treatment, especially of the form produced by malaria, as intimated in the heading of this paper.

But before proceeding to do so, it may be well to note that a so-called theory of albuminuria was recently presented at the Paris Academy of Medicine by M. Semmola, of Naples, with regard to its etiology—especially with reference to the chronic form called Bright's disease, viz.: That the malady is not essentially renal, but consists of a general, morbid alteration of nutrition; and he observes that albumen in such cases is not passed by the urine only, but by all the secretory organs. This alteration deprives the albuminoid materials of the blood of their power of being assimilated, and so causes their excretion by the emunctories. The renal lesions he ascribes to mechanical irritation of the tubules of the kidneys by the constant passage of albumen through them.

Albuminuria is, therefore, a cause, not a result, of renal disease. He founds these views on a series of experiments made on animals. He injected into the blood-vessels various substances containing albumen—as white of an egg, milk, and blood-serum—with the result of inducing artificial Bright's disease. White of egg was most active in this way. He therefore concluded that the more nearly albuminoids approach the character of serum-albumen, the less likely they are to injure the kidneys by irritation, and vice versa.

Admitting, however, the correctness of his deductions, we are confronted with the fact that there must be a cause of some kind not recognized or referred to by him, aside from the changes in the economy, to produce this excess of albumen in the blood, and the conjecture is a reasonable one that these very changes which he describes are quite likely to be produced by the poison, whatever it may be, that develops intermittent fever, as it is one of the most potent means of depressing the vital energies and sapping the foundations of health.

In the further elucidation of this subject as being caused largely by malarial influences, let us look at some facts undoubtedly familiar to most of the general practitioners who have lived and been engaged in their profession for a period of twenty years in the city of New York; viz., that in portions of the city where improvements have been going on most rapidly, as in excavating the earth for the purpose of erecting a block of buildings, not only in that particular street, but including quite an area of territory in the vicinity, there has been an increased amount of intermittent fever, with a more general association of malarial toxæmia among its inhabitants where chills and fever were not absolutely produced. In such neighborhoods we find a much larger proportion of cases of albuminuria, especially among the young and middle-aged, in contradistinction to the cirrhotic kidney which, as a rule, occurs in persons past the middle age, and arising from entirely different causes, as arterial degeneration, etc.

I have dwelt somewhat largely upon the etiology of this affection in order to emphasize certain points in the treatment which require modifications according to the greater or less amount of influence exerted by this subtle but deleterious poison. It is well known that in an ague chill the kidneys, as well as all the other internal organs, become congested; that a frequent repetition of this condition has a tendency to produce structural changes, especially of the kidneys; and that an interstitial change in these organs of a permanent character is more likely to occur than in any other of them, excepting, perhaps, the spleen—and although the albumen usually disappears from the urine after the subsidence of the chill and fever, still, this is not always the case, of which fact we have abundant evidence.

In a certain proportion of these cases, even after the chill and fever are brought under control, the urine will contain a small amount of albumen, which may continue for months or years without the patient being conscious of the fact, and unless he is being examined for some other ailment the physician, even, may not suspect any renal mischief. But after a variable period of time, when the ankles become œdematous, with shortness of breath on exertion, with cardiac hypertrophy and the general debility associated with these organic changes, he examines the urine, and at once discovers the cause of the patient's ailments.

First in the treatment should be prophylaxis, consisting, so far as possible, in not only removing the chills and fever by the appropriate use of quinine, but in using other remedies for a considerable time thereafter, in order to eliminate the malarial poison from the system, which can usually be done, providing the physician impresses upon the mind of his patient the necessity of continuing treatment for some time after the chills shall have entirely subsided; because by so doing the susceptibility of the system while living in a malarial region, as we are doing, is sensibly diminished. As experience has proved, the most important remedies for accomplishing this desirable result are arsenic and iron, the form which I am most accustomed to use being sol. potass arsenite, combined with the solution of the ferrous malate—five minims of the former, for an adult, to thirty of the latter, continuing the same until the usual health and vigor are fully restored.

In the early period of this form of Bright's disease, now under consideration, where we find albumen in greater or less quantities, there is often an absence of casts in the urine, but which will appear later on in the disease, and this fact is of diagnostic importance in contradistinction to the atrophic kidney, in which the casts are usually coexistent with that of albumen.

The prognosis is much more favorable in this variety of the malady than in the cirrhotic form, as there is not such complete degeneration of the different tissues of the body, including the kidneys, while the response from the use of appropriate remedies is much more prompt. I have notes of quite a large number of cases of this form of the disease, in some where it has existed for six, eight, and ten years, where the general health of the patients is much better than it was at the periods mentioned, and apparently less involvement of the kidney structure. In some, albumen has entirely disappeared, although the gravity of the urine remains persistently below the normal, while in others the albumen never entirely disappears, even when they appear in perfect health.

As an illustration of the effects of remedies, I will mention one case out of many where the treatment has been of similar character.

Mrs. G——, now thirty-eight years of age, married, with four children (besides one that died several years since), the youngest three years of age. Father died in the Utica Insane Asylum of general paresis. Mother died of apoplexy. Came under my observation six years since, on account of œdema of the feet and legs, with general anasarca, dyspnœa on the slightest exertion, anorexia, constipation, etc.

On examining the urine, found the specific gravity 1010, which on boiling and adding nitric acid showed three-fourths of the volume of urine in the test-tube to be albumen, but on repeated microscopical examination no casts were found. She had lived the first two years in Jersey, and the three preceding ones in Greenpoint, L. I., both notoriously malarial localities, in both of which she had been a constant victim to chills and fever. Had never had any trouble after her confinements, and always enjoyed good health previous to that time. She was passing but a small quantity of urine; recumbent position almost impossible. On account of the urgency of the case (she having taken quinine until the chills were broken) I put her upon a pill much used by my old preceptor, Dr. Beckwith, of Litchfield, Conn., more than fifty years ago, in all cases of dropsy, and which has of late been rediscovered and lauded in the periodicals by several writers as one of the most potent means yet discovered of increasing the renal secretions and removing dropsy, viz.: calomel, pulv. scillæ, and pulv. digitalis, gr. 1 of each *ter in die.*

As usual, within three days she was passing more than a gallon of water in the twenty-four hours, after which the dropsy soon disappeared, and her improvement was everything desired. Three days was all that was required in the use of the calomel pill. From this time to the present, although the urine has always contained albumen, the quantity has never approached the relative amount at that time.

As soon as the urgent symptoms had disappeared, I commenced the use of a pill composed as follows: ℞. Hyd. bichlor., chloride of gold and sodæ, of each one-twentieth grain; ferri pr. hydrogen, two grains. Of these pills she took one three times a day for several months, substituting ext. digitalis for the iron when there was any diminution in the quantity of urine. Also Fowler's solution of arsenic three times a day, commencing with five minims, and increasing to fifteen or twenty gradually as the stomach would tolerate it. These remedies were continued most of the time for a period of two years, with constant improvement. Since which time, or during the past four years (although there has always been a small quantity of albumen in the urine), she has had but little trouble, bearing one child in the meantime, when, during the latter months of pregnancy, she had more or less dropsy, for which she took infusion of digitalis with the bichloride of mercury.

She now appears and feels in every way well, and takes no medicine, excepting at times when she will recognize the old mental stupor of uræmic poisoning as being the same that she had during the first years of her illness, although nothing like so severe, when, for a few days, she will use digitalis infusion, and be in good condition again.

Had I the time I could give the history of a large number of cases of which I have notes taken at the time, which I have treated substantially in the same manner, and with nearly the same results, in both sexes, and of all ages.

Admitting the etiological factor, as suggested in this paper, recognized by most authors, I believe we have in the remedies mentioned a means of materially mitigating the severity of the symptoms, and of prolonging life, sufficient to warrant the more general adoption of the same. It is not claimed that the disease is wholly eradicated, but that by proper treatment, with care in food and dress and hygienic surroundings, life may be prolonged for many years, and a state of comparative health enjoyed.

The treatment of Bright's disease by the use of corrosive sublimate is not a new thing. Professor Willard Parker, as long ago as 1850, urgently recommended its use in this disease, and was such an enthusiastic believer in the remedial virtues of the same, that he repeatedly asserted, both in his lectures and in his private practice, that Bright's disease, when recognized in the early stages, could be cured by this remedy alone, in connection with proper hygienic and sanitary surroundings.

Dr. John C. Peters reports that the treatment of this disease by the use of bichloride of mercury began in New York more than forty years since, by Dr. J. A. Smith, and was followed by Drs. Griscom and Joseph M. Smith.

The number of cases noted by them was twenty-six; and the majority of them were very much improved, although the urine still contained albumen. It was given in doses of one-sixteenth, one-eighth, and even one-fourth of a grain, every four hours, in tinct. cinchona. Its effects in these cases was diuretic.

It will readily be perceived that the dosage was, in these last cases reported by Dr. Peters, too large and the frequency of its administration too great to be tolerated by the system for any length of time; hence its disuse which followed. The disease being essentially of a chronic nature, the remedies should be continued for a long time, and must be given in small quantities.

Nitro-glycerine has, in the hands of many observers, as well as my own, proved a valuable addition to our therapeutical resources in the affection under consideration, not as a curative agent, like the remedies above mentioned, but for favorably modifying certain unpleasant symptoms so often observed, such as dull throbbing headache, caused by deficient elimination of urea, with a diminished secretion of urine, the insomnia connected with the same, the palpitation of a hypertrophied heart, etc. Given in one-fiftieth-grain doses and repeated every two hours, it will do more to dissipate these unpleasant sequelæ than any other remedy with which I am acquainted. As soon as its specific effect is produced a sense of relief will follow, when the remedy should be withdrawn, only to be renewed when the symptoms may occur indicating its use.

Its effect is usually to promote the action of the kidneys and increase the flow of urine as well as the greater elimination of urea.

In summing up the points I wish to make, then, I should say that in my experience with this form of kidney difficulty, quinine should be given until the chills are broken, in doses of five grains three times a day; then smaller doses with iron (preferably the solution of the ferrous malate) until the cachexia is removed, after which give a pill containing each, grain one-twentieth acid. arsenious, chloride of gold and sodæ, and two grains Queevennes' iron, to be taken after eating, and continued for a long time. Also bichloride of mercury one-sixtieth grain, gradually increasing to one-twentieth grain (which should never be exceeded), dissolved either in tinct. cinchona or infusion of digitalis, the latter being preferable in the majority of cases on account of its action in steadying and slowing the heart, and by so doing increasing the urinary secretion. This, also, should be used three times a day. For the numerous troubles we have associated with the disease, glonoin will be found to more often relieve them than perhaps aught else. When dropsy occurs, as it often does, we have in calomel guarded by opium, one grain of the former with one-third grain of the latter, given three times a day, a very sure means of relief; but when giving this remedy all other medicines should be temporarily withheld. Where a person comes from a distance, or is to be absent for a considerable time, I am in the habit of prescribing two grains each of chloride of gold and sodæ, bichloride of mercury, and acid. arsenious, to be made into forty small pills, with the instruction to take one after each meal three times a day, and continue them until he or she returns.

By pursuing a course thus briefly outlined, persistently and steadily for a long period of time, the disease may be largely controlled and in many cases cured; but where this is impossible, as is unfortunately sometimes the case, its progress may be arrested and the patient may live in comparative comfort for a number of years. This is a plan of treatment I have pursued for many years with the most satisfactory results, and one I shall continue until some better means may be devised for arresting this terrible malady.

THE Post Graduate Schools have had a very successful season and have proved their utility to a large and widespread attendance of medical men. Both schools here are in a prosperous condition, and post graduate medical study in New York has come to stay.

A SERIES OF HEART LESIONS.[1]

By J. WEST ROOSEVELT, M.D.,
NEW YORK.

I PRESENT the following eight specimens of lesions of the heart which illustrate certain pathological and clinical facts worthy of note. In preparing these specimens I studied the records of eight hundred and fifty cases which came to autopsy at Roosevelt Hospital. The cases were taken as they came, and embrace various diseases and injuries. I looked for cases of valvular disease in which there was stenosis or insufficiency of a valve, or in which there were vegetations found on one. Cases of malignant endocarditis, and cases of valvular insufficiency from dilatation of the heart or ascending aorta, are excluded.

Among the 850 cases I find 123 of valvular heart disease, or 14.1 per cent. In these the mitral valve alone was diseased in 50; stenosis existed in 15; insufficiency in 27. Both stenosis and insufficiency are noted in 6; vegetations, not producing stenosis or insufficiency, in 2. The aortic valve alone was diseased in 24 cases. Stenosis existed in 2; insufficiency in 12; both, in 3; vegetations, not producing either, in 7. Both aortic and mitral valves were diseased in 44 cases. The following combinations were found: Aortic and mitral insufficiency in 13; mitral stenosis and aortic insufficiency in 8; aortic and mitral stenosis in 5; aortic stenosis and insufficiency, and mitral stenosis and insufficiency, in 3; aortic insufficiency and mitral stenosis and insufficiency in 3; aortic stenosis and insufficiency and mitral stenosis in 3; aortic stenosis, mitral stenosis and insufficiency in 1; vegetations on both valves, without interference with functions, in 2; vegetations on aortic valves with mitral stenosis, in 3; vegetations on aortic valves with mitral insufficiency, in 2; vegetations on mitral valve with aortic stenosis, in 1. The tricuspid alone was insufficient in one case. It alone was covered with vegetations in one case. In one case there were vegetations on the tricuspid, mitral, and aortic valves, the mitral being stenosed; and in one there was tricuspid insufficiency with aortic and mitral stenosis and insufficiency.

In these cases the most common lesions are those of the mitral valve. The next most common are combinations of aortic and mitral lesions. Then we find lesions of the aortic valves, and lastly, those in which the tricuspid, alone or in combination with other valves, is diseased. I would call attention to the rarity of cases of pure aortic stenosis, two only being found.

In the series the males exceed the females in the proportion of 94 to 29. The excess is due, partly at least, to the fact that many more males than females come to the hospital, and partly to the fact that in a number of cases death was caused by injuries to which the male sex is more exposed. A distinct history of acute articular rheumatism is found in 44, among whom 10 were drunkards and 1 had syphilis; 3 gave a history of both rheumatism and Bright's disease. Chronic diffuse nephritis seemed to precede the cardiac lesion in 20 cases, and in 5 of these there was a history of intemperance. A clear history of syphilis was noted in 6 cases, two being drunkards; none had had rheumatism. Alcoholism alone is mentioned in 7 cases. No mention of any of these causes occurs in 24 cases, as the histories are imperfect. In 7 all of them are denied; in 2, scarlatina and measles are noted. Four cases of sudden death are recorded, 3 with mitral insufficiency, one aortic insufficiency. In none of these cases was death sudden, in the sense of having been preceded by no symptoms, but the end came suddenly, the patients having done well before. Death occurred from accident or from disease which was not dependent upon the heart or kidney lesions in 22 cases. Uræmic coma or convulsions terminated 8; 3 died of cerebral hemorrhage, 3 of acute pericarditis, and the remainder died with the usual symptoms of dropsy, dyspnœa, etc.

---

[1] Read before the New York Pathological Society, February 22, 1888.

In attempting to draw any conclusions from these cases, the following points should be borne in mind: First, as to the relative proportion of cases of valvular disease to other diseases in hospital cases in New York, the number of autopsies studied is, I think, sufficient to show about the right proportion, namely about fourteen per cent. Second, as to the one hundred and twenty-three cases noted, no reliable deductions can be drawn, as they are not numerous enough. Third, the excess of males over females is probably too great, for the reasons mentioned. Fourth, in studying the etiology it must be remembered that in twenty-four cases the history is imperfect, and that these must be excluded. Fifth, that cases of sudden death do not often come under observation in a hospital, and are more frequent than the figures show. Sixth, cases dependent upon acute infectious disease are not fairly represented, because few children are treated in Roosevelt.

Bearing these facts in mind, we find that rheumatism was present in nearly forty-four per cent., chronic diffuse nephritis in nearly twenty per cent., syphilis in nearly six per cent., alcoholism alone in nearly seven per cent.; but that, taking cases with rheumatism, chronic diffuse nephritis, and syphilis, as well as cases without these, alcoholic excess was noted in nearly twenty-four per cent.

Aortic Insufficiency.—Calcareous Plates in Aorta Surrounding the Origin of the Coronary Arteries—Angina Pectoris.—Male, aged forty-six, admitted May 28, 1886. No rheumatism. Syphilis twenty-five years ago. Alcoholic habits marked at one time. No cardiac, pulmonary, or renal symptoms, except the attacks of angina. Attacks first began five weeks ago. First, has oppression in chest and dyspnœa. Then severe pain in *right* side of chest, radiating over whole front of chest; felt in both shoulders and both arms. During attack, fears immediate death. Shortly after admission, had an attack. The pain was severe. The radial arteries were hard and cord-like. Sweating profuse. Under amyl nitrite and magendie pain subsided for an hour. Then was seized with abdominal cramps without chest pain. Subsided under magendie. At 3 A.M., May 29th, after going to closet, patient returned to bed and suddenly died.

Autopsy May 29th, at 1 P.M., by Dr. Delafield. Rigor mortis very marked. Well-nourished man. All organs normal but congested, except the heart. The left ventricle is slightly dilated and thinned. The heart is not contracted, and the cavities contain a moderate amount of red clotted blood. The aortic valves are thickened and insufficient. A good deal of degeneration of the aorta. Just above the aortic valves the changes are very pronounced, and there is a calcareous plate which surrounds the origin of the coronary arteries. The coronary arteries themselves are perfectly normal. The mitral valve is a little thickened.

This case is interesting, as showing the relation of interference with the coronary circulation to attacks of angina.

Chronic Pericarditis with Adhesions and Calcification.—Aortic and Mitral Stenosis—Hypertrophy of the Left Ventricle—Absence of Chronic, Passive Congestion—Death from Slight Causes.—Christopher B——, aged fifty-six, German, married, conductor. Admitted to Roosevelt Hospital at 2.05 A.M., January 15, 1888.

Had been drinking hard for five or six weeks. Between 1 and 2 A.M., to-day, attempted to commit suicide by cutting both arms in the fold of the elbow. Wounds, about three inches long, had not divided the arteries. He did not seem to have lost much blood. He was conscious. Pulse fair strength, but rather rapid. Respiration normal. Had several slight convulsions, and died at 6.50 A.M. Heart was not examined during life.

Autopsy January 15, 1888, at 2.30 P.M., by Dr. Delafield. Body well nourished. Thick layer of subcutaneous fat. The wounds in the arms have only divided the superficial veins and have not injured the arteries. The organs generally were not anæmic. There was no congestion, such as is usual with heart disease. The liver was fatty. The kidneys were normal, save that the surfaces were a little irregular, and the fat about the pelvis was increased. The stomach, intestines, and spleen were normal. There were some old adhesions over the lungs.

I show you the heart. The pericardium is firmly adherent everywhere. In it, near the base, are some old calcific plates. Surrounding the tricuspid orifice, except that portion of it which is next to the mitral, is a ring of calcification which divides the auricle from the ventricle, and infiltrates the substance of the heart. The aortic valves are stenosed, and show numerous vegetations. The mitral valves are stenosed and thickened. Both of these valves show evidences of long-standing chronic endocarditis. The left ventricle is hypertrophied, but not dilated. There were post-mortem clots in all the chambers, and in the right ventricle some small ante-mortem clots.

The case is interesting, because it shows how little damage is done to the body in some cases by severe disease of the endocardium and pericardium. This heart must have been seriously crippled both by the valve lesions and the adherent pericardium, yet there was no passive congestion produced, nor did the man's nutrition suffer. Adhesions of the pericardium are not very uncommon. When such extensive lesions as those seen in this heart exist, one would expect much interference with the heart action, and marked symptoms and lesions of cardiac disease.

Another point of interest is that, although the man's heart seemed able to do its ordinary work, yet, after he had been on a prolonged debauch, a not severe hemorrhage was sufficient to kill him. He did not present the symptoms of severe hemorrhage. It is possible, of course, that, in addition to cutting his arms, he may have taken some alkaloidal poison, but he did not have symptoms of poisoning by any ordinary alkaloid, and it is most probable that his death was due to the exhausting effects of his spree and the slight hemorrhage, which were too much for the diseased heart.

Aortic Stenosis and Insufficiency.—General Dilatation of the Heart—Dilated Right Auricle Lying against the Chest Wall, at the Right of the Sternum, Causing Pulsation and Thrill, Simulating Aneurism.—Thomas K——, aged sixteen, admitted to Roosevelt Hospital August 3, 1881. Family history unimportant; denies syphilis, but has indulged in sexual intercourse; is temperate.

Rheumatism three years before admission. At that time had præcordial and epigastric pain, and has suffered from attacks of similar pain from time to time ever since. For one year has had frequent palpitation of heart and pretty constant dyspnœa, worse on exertion. Never had œdema of face or feet. Noticed no trouble with the urine. He has had frequent passing attacks of coughing, but during the past three months has suffered from constant cough, worse in the morning and evening, with mucopurulent expectoration. The cough is very violent, and sometimes a paroxysm produces vomiting. Never spat blood. For the last month has sweat much at night; has been losing flesh and strength.

On admission patient is cyanozed. Urine acid; specific gravity, 1.026; without albumen. Has marked dyspnœa and orthopnœa.

Physical examination: Marked visible pulsation of the superficial arteries; typical "water hammer" pulse; heart apex beat in sixth space, one inch to the left of left mammary line; impulse diffuse and heaving; area of dulness increased. In the first and second spaces to the right of the sternum is an area of dulness, about two inches in width, beginning at the right border of the bone. Over this area is felt a systolic thrill. Auscultation over the same area gives a loud, rasping, systolic, and softer blowing diastolic murmur. A systolic murmur is audible in carotids and subclavians on both sides, about equally clearly. At the level of the third right costal cartilage the quality of the systolic murmur is entirely different from that heard above and in the vessels. It is very sharp and whistling. The diastolic murmur also, at this point, becomes loud and harsh; it is transmitted down the sternum to the ensiform cartilage. A short, blowing, systolic murmur is heard at the apex and to the left of it. Systolic murmurs can be heard in both vertebral grooves. A double murmur is very distinctly audible in the left supraspinous fossa. Markedly exaggerated breathing and voice at the right apex. Over the rest of both lungs subcrepitant râles and diminished breathing.

The patient spat considerable blood a few days after admission. His dyspnœa improved.

During his stay in the hospital the patient had several attacks of severe dyspnœa, accompanied by severe pain in præcordium and down the left arm, and marked sweating. He also suffered at times from pain in the epigastrium, which radiated through to the back. After being in the hospital about seven months he was greatly improved. His attacks of pain became less frequent, the cyanosis disappeared, and on April 6, 1882, he was discharged improved.

I wish to direct attention to the fact that there was an area of dulness at the right of the sternum, in the first and second space, and that over this area a systolic thrill could be felt and a double murmur heard, and that there was well-marked "water-hammer" pulse. It is worthy of note that the quality of the double murmur changed at the level of the third right costal cartilage. It is possible that a marked increase in intensity may have been mistaken for a change in quality, but I think this is not so. A diagnosis of aneurism of the ascending arch, with aortic stenosis and insufficiency, was made at the time of his discharge.

The patient was readmitted June 21, 1884. After leaving the hospital he remained in pretty good health, suffering apparently at times a little from præcordial and epigastric pain. He was able to work, however. He had some cough. Two weeks before readmission, after exposure to cold and damp in an ice-house, cough became worse, and he suffered from cramps in the abdomen and legs. He also had pain in the right side of his chest; he lost appetite; sweats a good deal.

On admission he suffers from pronounced orthopnœa; has severe dyspnœa on exertion; urine alkaline; specific gravity, 1.030; albumen abundant; epithelial and hyaline casts.

At this time there are numerous moist râles heard over the bases of both lungs. Heart apex beat in same position as before. Diffuse and heaving impulse. Cardiac dulness enlarged. In the first, second, and third interspaces, for a distance of about one inch to the right of the sternum, there is dulness, and distinct pulsation with systolic thrill. Harsh systolic murmur can now be heard over the whole chest. Diastolic murmur audible the whole length of the sternum. Visible pulsation of carotids and subclavians, and over these vessels a systolic thrill. Finger in supra-sternal notch is lifted with the systole. Water-hammer pulse. Præcordial bulging.

Patient suffered from dyspnœa pretty constantly. He had a number of angenoid attacks. Profuse sweating was a prominent symptom. Orthopnœa was present until the end. On June 27th, at 4.10 A.M., became cyanotic. At 4.20 died.

Autopsy made by the writer eight hours after death. Body poorly nourished. Rigor mortis fairly marked. Brain not examined. The kidneys, spleen, intestines, and stomach were in a condition of passive congestion. The liver was firm and congested, and the upper surface showed a depression where the enlarged heart had rested upon it. The left lung was in a condition of pigment induration. The right pleural surfaces were everywhere adherent. The lung was in a condition of pigment induration. The lower lobe was compressed by the enlarged right heart. The bronchi were congested in both lungs, and contained muco-pus.

The heart weighed two pounds when emptied of clots. All of the chambers were dilated, their walls were about as thick as those of the normal heart. The aortic valves were stenosed and insufficient. One cusp is almost gone, and the others are thickened. Mitral valve thickened, but seems sufficient. Tricuspid and pulmonary valves normal. The dilated right auricle lay against the chest-wall behind the second and third ribs to the right of the sternum, and it was this which had given the dulness, thrill and pulsation described. The aorta was healthy and not dilated.

The case was peculiar because of the close resemblance to aneurism in the physical signs. When the patient returned after an absence of two years from the hospital, it was thought that, if he had had an aneurism, it would probably have killed him before that time. The absence of symptoms of pressure upon the trachea or bronchi, œsophagus, or recurrent laryngeal nerves, and the absence of pain in the neighborhood of the pulsating area at the right of the sternum, together with the youth of the patient, were all against aneurism. On the other hand, the dulness, thrill, and pulsation on the right of the sternum were pretty strong evidence in favor of that diagnosis.

ACUTE PERICARDITIS WITH EFFUSION COMPLICATING DOUBLE LOBAR PNEUMONIA.—Male, aged nineteen. Laborer. Austria. Admitted February 13, 1888. History imperfect, because patient could speak no English. Sick eight days. Pain in right chest. No chill. When admitted was very weak. Restless. Pulse weak, 94. Respiration, 34. Temperature, 102.8°. Extreme dyspnœa. Urine, specific gravity 1.019; trace albumen; to casts. The physical examination gave signs of consolidation over lower part of both lungs, behind. Over the right chest, in front, the resonance was normal. The breathing and voice were normal from the apex to the second rib, and thence to the bottom were broncho-vesicular. Over the left chest, in front, dulness began at the second rib and was found from thence down. Breathing broncho-vesicular. Heart apex in normal position. Sounds obscure, but no murmur. Patient sank and died February 15th, at 8.10 A.M. Autopsy showed red hepatization of lower lobes of both lungs, with a very thick layer of fibrin on the right side. The hepatized right lung had prevented the pericardial fluid from distending the sac on that side. The left lung was pushed backward and upward by the pericardial effusion. The pericardium was distended with purulent serum. I show the heart, which has no endocardial lesions. The visceral and parietal layers are covered with a pretty thick layer of recent fibrin.

The case is interesting because of the position of the effusion caused by the right lung, and also as illustrating a not infrequent, but often unrecognized, complication of lobar pneumonia. The absence of friction sound, I presume, was due to the effusion. Possibly, could the patient have been made to lean forward, it might have been heard.

ADHERENT PERICARDIUM.—This heart was taken from the body of a man who died in Roosevelt Hospital July 18, 1886, of meningeal hemorrhage. No history could be obtained, except of the fatal apoplectic attack. The autopsy showed meningeal hemorrhage and some phthisis. There were no evidences of chronic venous congestion. The visceral and parietal layers of the pericardium are everywhere firmly adherent. The walls of both ventricles are somewhat thinned. The valves are normal.

This lesion is not very rare. It is probably but rarely diagnosed during life, however. I looked through the records of the autopsies made at Roosevelt Hospital since 1880, and among these I find a number of cases. The lesion does not necessarily do the patient much harm, when uncomplicated by valvular disease, or at least it may exist for some time without producing the ordinary lesions of passive congestion. In this case there were no evidences of such congestion.

In another case, a young man of extraordinary muscular development worked as a roofer, and carried very heavy weights, and gave absolutely no history of anything pointing to heart disease. He died of disease of the ependyma with serous effusion into the ventricles of the brain. His pericardium was firmly adherent throughout; the heart, otherwise, was normal. There was no history of rheumatism or syphilis, and the time at which the adhesions were probably formed is unknown.

In looking for other cases I find only two in which the lesion was uncomplicated by valvular disease. In one, there was also chronic peritonitis and ascites, and the heart was normal, save for the adherent pericardium. The other was a case of tubercular pericarditis, which has been reported to this Society. In this case the heart-muscle was much thinned. In neither of these cases was a diagnosis made. As very little is really known about the physical signs produced by this lesion, I tried to see whether the records would throw any light upon them. In the case of the young man who died of disease of the ependyma, the heart is recorded as normal. In the case in which chronic peritonitis existed, it is simply stated that the heart action was irregular, intermittent, and feeble, and that there were no murmurs. In the case of tubercular disease, it is recorded that the heart impulse was imperceptible and the heart action weak. In another case of complete adhesions, which were very thick, there were no signs noted save the murmurs caused by complicating stenosis and insufficiency of the mitral valves. A fifth case gave the usual murmurs of aortic stenosis and insufficiency and mitral insufficiency which existed, and, in addition, it is noted that "there was visible pulsation with perceptible impulse in the third, fourth, and fifth spaces at the left of the sternum." In a sixth case, with thickening and insufficiency of the aortic and mitral valves, the usual murmurs were heard and the impulse of the heart was felt in the sixth space, nipple line, and is noted as "forcible, but diffuse."

These, with one mentioned in another part of this paper, are the only cases I could find in which the physical signs are recorded. In none, so far as I could ascertain, was a diagnosis made of the pericardial lesion. It is probable that the possibility of its existence may have been forgotten, and that, therefore, some more distinctive signs were overlooked. It is very likely that, in all of the cases, the apex beat would have been found not to change its position when the patient's attitude was changed; and it is possible that the impress on the left of the sternum noted in the fifth case may have occurred with diastole, and not with systole. I shall not weary you by mentioning the physical signs usually described as indicative of this condition, but simply record the cases and call attention to the difficulties in diagnosis in adults.

MITRAL STENOSIS AND INSUFFICIENCY.—TRICUSPID INSUFFICIENCY—DILATATION OF BOTH AURICLES AND OF THE RIGHT VENTRICLE.—Patient, a boy aged fifteen, had scarlatina, followed by some pains in the joints, twelve years ago. Came under observation January 26, 1888. No history of cardiac symptoms until three weeks ago. Then cough, followed in a week by œdema of the feet and legs, abdominal swelling, and some dyspnœa. Grew rapidly worse. Dyspnœa and orthopnœa became extreme. Remained in hospital for about three weeks and was then taken home. Died February 15th. When admitted to hospital, urine was acid, specific gravity 1.027, small amount of albumen. He was very dropsical, and suffered much from dyspnœa and orthopnœa. The apex beat was in the fifth space, nearly in the left anterior axillary line. Impulse was diffuse and slapping, and could be seen causing indentations in the third, fourth, and fifth spaces to the left of the sternum. There seemed to be a drawing in of the lower part of the præcordium with the systole, but the heart action was too rapid to be sure of this. A distinct systolic thrill could be felt over the whole præcordium. Area of cardiac dulness enlarged. Systolic pulsation of veins of neck very marked. Rough loud præsystolic murmur audible to the left of the sternum from the third rib to the apex. This murmur sounded almost like a friction sound. Systolic murmur over whole præcordium, loudest above the apex, transmitted to the left, and heard in the left vertebral groove. Pulmonary second sound much accentuated. The pulse was small but regular, 110; respiration, 28; temperature, 101.8° F. There were signs of fluid in both chests and abdomen. The apex beat was hardly at all changed in position by such changes of posture as the patient could be made to take, but owing to his distress it was not possible to test this point thoroughly. From the signs I thought the boy had mitral stenosis and insufficiency, with dilated right heart; and from the apparent systolic depression thought he probably had an adherent pericardium. At the autopsy we were only permitted to examine the heart. There was ascites and hydrothorax. The pericardium contained a very slight excess of fluid, but was otherwise perfectly normal. The heart I present to you. The left ventricle is very slightly dilated. The aortic valves are very slightly thickened, and on one cusp is a small recent vegetation. The mitral valve and chordæ tendinæ are very thick. The cusps of the valve are glued together so as to make a rounded opening less than one-fourth inch in diameter, which evidently cannot be closed. The left auricle is dilated and thickened, its endocardium is thickened and white. The right ventricle is much dilated; the tricuspid valves are much thickened, their chordæ tendinæ are thickened and shortened. The right auricle is much dilated. The pulmonary valves are normal. As the heart lay in the chest the dilated right ventricle was in front of the left, and so great was the dilatation that the heart had been caused to rotate on its axis, so that the left ventricle was not only behind, but its left border was about one inch to the right of the right ventricle. The dilated right auricular appendix pressed upon the aorta, lying between it and the chest-wall.

MITRAL STENOSIS, AORTIC STENOSIS, AND INSUFFICIENCY.—TRICUSPID INSUFFICIENCY—GENERAL DILATATION OF THE HEART WITH HYPERTROPHY—SYSTOLIC MURMUR MOST DISTINCT AT THE APEX.—The patient's history is of the ordinary symptoms of cardiac disease for one year. He was fifty-two years of age. He had had rheumatism, scarlatina, chancroids, and gonorrhœa. The only point of interest for my present purpose is that the only murmur audible was a systolic one, which could be heard over the whole præcordium, but was most distinct at the apex.

His heart is hypertrophied and dilated, and there is calcification, with stenosis and insufficiency of the aortic valves; very close stenosis of the mitral valve, and well-marked insufficiency of the tricuspid valve.

In connection with this case I show another heart with stenosis and insufficiency of the mitral valve, in which a systolic apex murmur alone was audible.

In the records of the Roosevelt Hospital I find the following cases, which are of interest when considering the relations of heart murmurs to lesions. It is needless to say that they are all cases in which an autopsy was made:

1. Area of cardiac dulness enlarged. Feeble and irregular action. No murmurs. Lesion: Aortic stenosis and insufficiency. Mitral insufficiency. Hypertrophy with dilatation of left ventricle.

2. Heart enlarged. Feeble and irregular action; no murmur. Aortic valves thickened. Mitral valves stenosed. Hypertrophy of right ventricle.

3. Systolic apex murmur. Lesion: Mitral valve stenosed, and insufficient and calcified. Hypertrophy with dilatation of right ventricle. Slight dilatation of left ventricle without hypertrophy.

4. Systolic apex murmur, loudest at the lower end of the sternum. Lesion: Aortic insufficiency. Mitral stenosis and insufficiency.

5. Loud systolic murmur over the whole præcordium. Lesion: Aortic valves calcified, rigid, and insufficient. Mitral a little thickened. Great dilatation of left ventricle.

6. Systolic apex murmur. Lesion: Stenosis and thickening of the mitral valve. General hypertrophy and dilatation.

7. Systolic base murmur. Force of heart action great as compared with feeble pulse. Lesion: Mitral stenosis so marked as nearly to close the valve.

8. Forcible impulse against chest-wall. Irregular action. Heart-sounds obscure, but no murmur. Increased area of præcordial dulness. Small, weak pulse. Lesion: Hypertrophy of right ventricle. Thickening and stenosis of mitral valve. Marked thickening of the endocardium of the left auricle. Left ventricle normal.

9. Loud systolic murmur heard at apex, and transmitted to the left. Diastolic murmur over aortic valves, and transmitted down the sternum. Lesion: Dilatation and hypertrophy of the left ventricle. No valvular disease. This patient died of uræmia, due to atrophic chronic diffuse nephritis. It seems probable that the dilated heart permitted regurgitation through the aortic and mitral orifices during life.

10. Heart action forcible; rhythm somewhat irregular. A loud systolic, rough murmur heard over the whole præcordium, loudest at apex, and transmitted toward the axilla. No mention of possible transmission up great vessels. Lesions: Left ventricle normal. Right ventricle somewhat dilated. Pericardium distended with clear serum. Mitral and aortic valves are both much thickened and stenosed.

11. Double murmur, heard loudest at the apex and transmitted to the left. Lesion: Aortic valves covered with old vegetations, ulcerated, and partly calcified. Old pericardial adhesions.

Of course, it is well known that murmurs do not correspond to lesions with absolute exactness, but it is interesting to see how little relation they may have to valvular disease. Among these cases are two with feeble and irregular action, but no murmurs, although the valves were diseased. The feebleness of action may have explained the absence of the murmurs. The murmur produced by mitral stenosis, if we may judge from these cases, is sometimes systolic and loudest at the apex, sometimes systolic and heard only at the base, and sometimes not audible. I do not speak of these cases as showing anything new, but I wish merely to emphasize something old and well known, but often forgotten. I do not wish to waste words, as some are now doing, by theorizing about the mode of production of murmurs; nor to worry about the possibility of the murmur of mitral stenosis being caused by systole of the auricle or the ventricle; nor whether it should be called "præsystolic," or "post-diastolic," or anything else. We have a murmur which precedes the first sound, and is usually only heard at or near the apex, and this indicates mitral stenosis. The murmur is of a generally peculiar quality, and begins softly and ends much louder. We have also in mitral stenosis a murmur of the same quality, which may take the place of the first sound; we may have no murmur, or the murmur in some cases seems actually to follow the sound. These facts are important. As for the theories, we do not know enough yet to really prove any of them. The Pathological Society is not a place in which we should discuss theories too much. The aim of these meetings is to give opportunities to study lesions and to learn from facts. From the study of lesions we can say: That extensive valvular disease may exist without murmur; that murmurs are not always heard in the situations usually described, nor are they always transmitted in the classical manner; that the murmur of mitral stenosis is peculiarly apt to be irregular in its time and situation; and finally, that although basic systolic murmurs, transmitted up the great vessels, are not uncommon, yet aortic stenosis is a rare lesion, and these murmurs usually only indicate disease of the valves without stenosis. I repeat that I present these facts not because they are new, but because they are so often forgotten.

In conclusion, let me summarize the facts which I have desired to illustrate by this series of hearts.

First, the specimen of calcareous plates in the aorta, obstructing to a considerable degree the coronary circulation. This specimen shows the influence of obstructed coronary vessels in producing angina pectoris.

Second, the case of pericardial adhesions and calcification with valvular disease. The point of greatest interest here is the death of the patient from a slight hemorrhage. It shows how feeble is the vitality in some cases of organic heart disease, even when the lesion of the heart has neither yet interfered with the nutrition of the patient nor produced passive congestion.

Third, the case of adherent pericardium is presented, with the epitomes of other cases, to call attention to the lesion, and also to the fact that its diagnosis is not easy.

Fourth, the acute pericarditis complicating pneumonia is presented to show the lesion, and to bring to mind a complication often overlooked.

Fifth, the case of valvular disease with general dilatation, and with dilated right auricle pulsating to the right of the sternum, is reported because of its resemblance to aneurism.

Sixth, the case of extreme mitral stenosis and insufficiency, with tricuspid insufficiency, is interesting because of the lesion and the physical signs.

The seventh and eighth cases, and the histories of certain others, illustrate the peculiar physical signs produced by some valvular lesions.

Clinical Department.

UNUSUAL CASE OF CANCER.[1]

By T. H. SQUIRE, M.D.,

ELMIRA, N. Y.

Edward M—— died suddenly on Wednesday, November 9, 1887, aged fifty-one. For years his business had been to measure and sell lumber in connection with a planing mill, and he was a man much relied upon in this capacity. He carried in his right hand a long, flexible, wooden rule, tipped with a brass flange, which he hooked on to the boards and planks and light timbers, turning them over and moving them as his business required, and thus his right hand and forearm did a great deal of hard and peculiar work, continuously, for many years.

About four years before his death he began to feel pain in this forearm, extending to one or two of the fingers. This pain gradually became more and more constant and severe. It was called rheumatism and neuralgia. Several physicians, in succession, were consulted, and many remedies were used to overcome the pain, but all of little or no avail. The forearm began to enlarge, and he began to lose perfect use of some of the fingers. Finally the forearm and hand became nearly useless, the fingers rigidly flexed, the wrist somewhat flexed, the muscular part of the forearm swollen, hard, and the seat of constant and increasing pain. Treatment seemed to have no influence in staying the progress of the disease, and nothing but opiates could materially lessen the pain. The time came when amputation above the elbow was advised, and then he consulted Dr. Thomas Markoe, of New York, who coincided in this measure. The amputation took place on January 22, 1887, at the junction of the lower and middle thirds of the humerus. At that time the patient was greatly prostrated by long suffering and general poor health. He had done no work for more than a year. He began very quickly to improve after the amputation.

The amputated member was sent to Professor Markoe, through whose kindness, in due time, the following report was received from the pathologist of the New York Hospital:

"The muscles of the right forearm are involved extensively by an interstitial lesion, which extends from a level four centimetres anterior to the elbow-joint down to the junction of the middle and lower thirds of the forearm.

---

[1] A paper read before the Elmira Academy of Medicine, February 1, 1888.

All the muscles in front and on the sides of the forearm are involved, except the flexor carpi ulnaris and the extensor carpi radialis longior.

"The tissues of the forearm anteriorly are extensively broken down. There is a soft, pulpy, reddish mass of broken-down tissues, extending from the middle of the forearm upward a distance of seven centimetres. This broken-down area is ovoidal in shape and five centimetres in diameter. Surrounding this mass there is a great increase of fibrous tissue at the expense of the muscles. The nerves and blood-vessels cannot be satisfactorily traced through the affected region. The bones of the forearm are not invaded, but the connective-tissue thickening is continuous with the periosteum. The walls of the larger vessels show no variation from the normal to the unaided eye. There is contraction of the fingers and thumb, and the hand is slightly flexed. The tissues everywhere along the line of the incision in the amputation are healthy.

"The microscope reveals great thickening of the walls of the smaller arteries and capillaries, extensive capillary obliteration, and very extensive endarteritis obliterans. There are extensive areas of inflammation along the planes of the fibrous tissue, in places giving the appearance of granulation-tissue. Diagnosis—myositis interstitial.

"(Signed,) F. FERGUSON."

In a brief note accompanying this report Professor Markoe says: "At first the pathologist was inclined to pronounce it sarcoma, and he showed me some sections that looked like it; more thorough study, however, brought him to the conclusion that it was essentially an inflammatory condition of the muscular tissue itself."

Mr. M—— continued to improve in his general health, after the amputation, for about four or five months. The stump healed kindly, he gained in appetite, was free from pain, and he became engaged in business which did not require any special physical exertion. But in the middle of the summer he began to have a pain in the upper third of the right thigh, and he was observed to limp in walking. He began also to have a slight cough. These symptoms continued and others supervened, so that it was not long before he was again confined to the house. He was obliged to lie on the bed, or on a lounge, with the right thigh and leg flexed. A peculiar tubercle was discovered in the substance of the lower lip just beneath the skin and a little to the left of the median line. It continued to approach the surface, the skin gave way, and a small circular and very indolent ulcer appeared there. It was not painful. It never healed, but very slowly grew larger, involving the skin and deeper tissues nearly to the bone. At the time of his death it was still circular in outline and half an inch in diameter. There was scarcely any discharge from this sore. It never bled. During the month of August, and afterward, other subcutaneous tubercles began to show themselves in different parts of the body. A little group of them were felt like small shot beneath the skin, or in the lower stratum of the skin, on the lumbar region, to the left of the spine. This group was composed of four tubercles so near to each other that, as they enlarged, they touched each other, and at the time of his death they occupied a space one and one-half inch in diameter, and the skin had given way over the largest one of the group. After death I removed them in mass and laid them open with the knife, finding the interior of each tubercle a broken-down tissue of dark venous color, nearly black, suggestive of the melanotic variety of cancer. At the time of his death there were tubercles of this character, in various stages of development, on different parts of the chest, neck, abdomen, back, thighs, and other parts of the body. The hip-joint was the centre of the most of his pain. Toward the close of his life the disease made rapid progress in the lungs. He first coughed blood on November 3d, and on November 9th a fatal hemorrhage from the lungs took place. There was no post-mortem examination.

There is no evidence of any marked hereditary taint in the family. His father is still living.

SOME RANDOM CLINICAL NOTES.

By MARCELL HARTING, M.D.,

BUFFALO, N. Y.

A QUESTION FOR CHEMISTS.—Twice I have observed a curious effect of chloroform, which I have not seen mentioned in the literature. Upon chloroforming a patient, my friend Dr. Bode began coughing so violently that he almost vomited. A second time, a robust lady was helping, and she started in the same strain, and actually vomited, while I myself felt only a scratching in my throat. Undoubtedly, this is an effect of the gas-lights upon the vapor of chloroform. But what gas is produced? It is not chlorine, as it has no odor.

PUERPERAL CONVULSIONS.—We expect such where intense nephritis and general œdema exist during confinement. I saw such a case of late, three weeks before confinement. Digitalis was of some slight benefit. During the confinement, which a midwife attended to, no convulsions occurred. Three months afterward the woman was nursing her baby, the œdema had vanished except in the face, but suddenly perfect coma supervened, from which she was restored again after ten hours. The urine remained as full of albumen as before. Urinous smell of the breath was never perceptible. This case shows that, even in the most pronounced case of parenchymatous nephritis, puerperal convulsions do not necessarily appear.

PHOSPHORUS IN RACHITIS.—I wonder that medical men are so divided in their opinions concerning the efficiency of this remedy. Not many cases occurred in my practice since Kassowitz published his observations, but those I had to attend were among the very worst I have seen, and the results, compared with those of former treatment, were simply marvellous. One child, which was already three years of age, could not walk a step. Forearms and legs were distorted in all possible shapes; the large fontanella was enormous. In four weeks it walked, and the fontanella was almost closed. In another case, almost as bad, with laryngismus stridulus, the result was the same. The explanation of the differences of results by Casali seems to me deficient in one point; *i.e.*, I do not think rickets can be mistaken for arrest of development by a half-way competent observer. A puny, ill-nourished child is not a rickety child, but where decided swelling of the epiphyses, the "rosary" at the ends of the ribs, and softness of the os occipitale exist, there is rickets, whether laryngismus stridulus exists or not, whether the swollen epiphyses are painful (a too subjective symptom for a test) or not. The idea, again, that phosphorus can make up the deficiency of phosphorus in the bones is simply ridiculous, because one-third to one-half grain for a whole month can only act as a peculiar stimulant, as proven by Wegner, who showed that healthy bones became eburnated. Another fact demonstrated by Wegner, namely, that granular atrophy of the liver follows the prolonged exhibition of minute doses of phosphorus, must not be forgotten, and phosphorus must not be exhibited too long. One month is enough, and if more should seem necessary I should certainly interpose one month without the drug. Research is desirable as to the question how long impunity exists—I mean, how long we do not risk a granular atrophy of the liver. The want of results with some observers remains unexplained.

SUBCUTANEOUS DRAINAGE IN ASCITES.—I proposed this once in THE MEDICAL RECORD, but have not heard of anybody having tried my plan. I myself had only one opportunity. There I was prevented from going further than inserting a double thread of stoutest braided silk in a loop. I hoped it would act like a lamp-wick, and it did so for a few days; great œdema of the labia and neighborhood of the pubes was the consequence. This disappeared in a few days, and the thread ceased to act as a drain. It remained, though, aseptically embedded till death. A simple subcutaneous puncture would not do either. My original plan of inserting a tube, at least a decalcified-bone tube or an artery of an animal treated like catgut, ought to be tried next; if they should cease to act too soon, nothing less than rubber or hard rubber would do. If the œdema, especially at the start, should appear too great, a puncture with a trocar should be performed simultaneously with the operation.

GENU VARUM OR VALGUM.—Though I have not executed it, I take the liberty of proposing a new operation. In the large majority of cases the cause of genu valgum or varum is an uneven growth of the internal or external condyle of the femur. In valgum, whether always I will not say, but since I paid attention to it I saw deficient development of the external, and in varum of the internal condyle. The correct conclusion, then, is: If we would make the lesser condyle grow quicker we would restore the equilibrium, *i.e.*, cure the deformity. For this purpose it may be sufficient to implant into the condyle a disinfected ivory nail. Irritation causes reaction, and if the irritation would be produced in the aseptic manner mentioned, I should expect just enough reaction to cause the condyle to grow to a proper size. Danger and suffering are not to be anticipated, for the condyles are on both sides easily accessible. Ogston's and Macewen's operations are formidable as compared to the one I am proposing, while theirs are not in such conformity with physiology and pathology.

VERATRUM VIRIDE IN PUERPERAL CONVULSIONS.

BY J. S. PRETTYMAN, JR., M.D.,

MILFORD, DEL.

I VISITED Mrs. W—— at eleven P.M. on February 16th. She is thirty-eight years of age, married, and was pregnant, at full term, with her eighth child. Dropsy was general and decided. Her previous labors were normal and easy. She complained of severe pain over the region of the stomach, and had vomited freely without relief. At noon she ate a hearty dinner of ham, cabbage, etc., and this returned from the stomach undigested. I administered morphiæ sulph. gr. $\frac{1}{3}$ hypodermatically, and in half an hour left her resting quietly. She remained comfortable until 1 A.M., when local spasmodic contractions began, and I was again summoned.

In fifteen minutes I entered her room, just as she was seized with a hard convulsion. I gave her ♏x. of tr. veratrum viride hypodermatically, and in half an hour, another convulsion occurring, I repeated the dose. As soon as she recovered consciousness I also gave her, by the mouth, ♏v. of veratrum, with ʒ iij. of tr. lobeliæ compound (Am. Dis.) in hot water. She retained this, and did not vomit until after the third convulsion, which occurred in an hour from second, when I again gave ♏x. of veratrum hypodermatically, as before. The drug was continued, by the mouth, in six-drop doses, every hour, until 6 A.M., when patient was thoroughly relaxed and nauseated, with pulse at 58.

She was perfectly conscious until 8 A.M., when her first labor-pain was felt. A second pain came on in five minutes, and the child was expelled. Instantly she went into convulsions, before the cord was severed, and I again repeated the veratrum (♏x.), subcutaneously, and continued the same, by the mouth, in six-drop doses, every two hours, until noon. No other convulsions having occurred, I then withdrew the veratrum, and ordered tr. bellad. in ten-drop doses, every three hours, rather as a placebo, but at the same time having regard for its action upon the vaso-motor system and hoping to slightly overcome the excessive relaxation.

The day was passed without further trouble until five in the evening, when she was again seized with a convulsion, and I gave her ♏xv. of veratrum hypodermatically, and continued the same in four-drop doses, every two hours, through the night and succeeding day. I attribute this convulsion, which was her last, to the action of the belladonna in increasing the vascular tension, for five minutes before it occurred her pulse was 85, and firm and hard.

A microscopic examination of the urine passed at six o'clock on the morning of the 17th revealed many large epithelial and granular casts, while the heat-test indicated in bulk one-half albumen. I have several times since examined the urine, and find that the casts and albumen are both gradually disappearing.

The ease with which the child was born and the freedom from hemorrhage were remarkable. I have never been present at a birth where so little blood was lost, the placenta being itself almost dry.

WILL THE INDUCTION OF PREMATURE LABOR RESTORE SIGHT IN THE ALBUMINURIC RETINITIS OF PREGNANCY?

BY GEORGE STERLING RYERSON, M.D., C.M.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY, TRINITY MEDICAL SCHOOL, TORONTO, CANADA.

IN THE MEDICAL RECORD of March 3d the question is asked by Dr. J. L. Thompson, of Indianapolis: "Is it ever justifiable to provoke premature labor for the restoration of sight in albuminuric retinitis?" He is of the opinion that it is justifiable, and quotes cases in support of his contention. I was of this opinion so long ago as 1881, and I am pleased to find myself in such good company as that of Drs. Loring, Pooley, and Thompson. In a matter so important as this, I think all cases bearing on it should be put on record. I submit the following one. My notebook says:

"Mrs. E——, aged twenty-two. June 1, 1881. Referred to me by Dr. Temple. Is in the fourth month of first pregnancy. Complains of severe headache and vomiting. Her sight has been failing for a month. She could see well before. Everything seems hazy to her. V., R., counts fingers at five feet, reads 16 Jaeger. V., L., fingers at three feet, reads 20 Jaeger. On examination with the ophthalmoscope the usual signs of retinitis albuminurica are found in a marked degree in both eyes. The urine contained a large amount of albumen. She was advised by Dr. Temple and myself to have labor brought on, but declined doing so. Three weeks later she was seized with uræmic convulsions. Labor was induced, and she recovered on August 4th. V., R. and L., $\frac{20}{50}$, 16 Jaeger. She could see to write a letter. The patches in retina still remained, but there was less swelling, and the extravasations were disappearing. Late in fall of the same year she again became pregnant, and the sight again failed. During the fourth month of her second pregnancy she was again seized with uræmic convulsions, became comatose, and died."

SOME ETHICAL REFLECTIONS.—"If your work is first with you, and your fee second, work is your master, and the Lord of work who is God. But if your fee is first with you, and your work second, fee is your master, and the lord of fee who is the devil."—*Ruskin.*

"He who is jealous of a rival acknowledges his own inferiority." This is an old aphorism, but specialized by a Detroit doctor for the benefit of the profession.

"The prime qualities of a physician may be summed up in the words: *Cassax*, *perspicax*, *sagax*, *efficax*. *Cassax*—there must be room to receive, and arrange, and keep knowledge; *perspicax*—senses and perceptions, keen, accurate, immediate, to bring in materials from suitable things; *sagax*—a central power of knowing what is what, and what it is worth, of choosing and rejecting, of judging; and, finally, *efficax*—the will and the way—the power to turn the other three—capacity, perspicacity, sagacity, to account in the performance of the thing in hand, and thus rendering back to the outer world, in a new and useful form, what you have received from it."—JOHN BROWN, M.D.—*Horæ Subsicivæ.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, March 24, 1888.

THE FUNCTIONS OF THE SUPRARENAL CAPSULES.

THE question of the uses of the suprarenal capsules is one that has heretofore quite baffled the researches of physiologists, the weight of opinion being that they were fœtal or rudimentary bodies, having no especial function in the adult life of man. A careful study of the subject, however, has recently been made by Dr. C. A. Macmunn (*The British Medical Journal*, February 4, 1888), with the result of furnishing a very plausible theory as to these organs, and of rehabilitating them into functional importance in the economy.

Dr. Macmunn shows, first of all, that from the point of view of comparative anatomy the suprarenal capsules are not rudimentary structures, but that they increase in relative size and anatomical complexity with the rise in the scale of animal life. They are formed in part from the ectoderm and in part from the mesoderm. The ectodermal part is furnished by sympathetic ganglia, and it forms the medullary or nervous portion of the gland. The mesodermal part forms the cortical or glandular portion. In mammals this part predominates, making of the capsules an essentially glandular organ. The increase in size and importance of the suprarenals in birds and mammals, as compared with fishes and reptiles, corresponds with the increase of the respiratory pigments.

As to the physiological chemistry, there have been found certain chromogens (Krukenberg), besides hippuric and taurocholic acids—benzoic acid, taurin, and inosit. The presence of these products indicate a very active downward or retrograde metamorphosis.

Dr. Macmunn has found, by spectroscopic test, the bands of hæmochromogen or reduced hæmatin. Now, this substance is never found in any but excretory fluids of the body (liver, bile). Hence it is concluded that the suprarenals have an excretory function. He also found substances, such as histohæmatin, which are antecedent to the hæmochromogen. This fact supplied additional evidence that the capsules were excretory bodies.

If these glands are excretory, it ought to follow that in Addison's disease, involving the suprarenals, and impairing their function, the urine would contain incompletely metabolized pigments. This is exactly what he did find. In the urine of Addison's disease he observed a peculiar pigment which he calls urohæmatin, or, more strictly, "urohæmato porphyrin." This pigment is only found in the urine when an excess of effete hæmoglobin is present in the circulation, so that the blood-glands are unable to use it up; or when the hæmoglobin being normal, the blood-glands are diseased and cannot reduce it, as in cirrhosis of the liver, Addison's disease, and Hodgkin's disease, involving the suprarenal capsules, and causing bronzed skin. Since in many cases in which he found this pigment the only glands diseased were the suprarenals, these, he thinks, must be blood-glands.

In cases of Addison's disease there are often very severe nervous symptoms of a depressive character, combined with hyperthermia or subnormal temperature. The symptoms sometimes resemble those of sepsis. Foa and Pellacani found that aqueous and alcoholic extracts of the suprarenals injected into the veins of rabbits produced toxic phenomena of a severe and characteristic type. The poison was of a septic nature, causing, finally, paralysis of the spinal cord and of the bulbar centres. It was believed to be a nitrogeneous, non-crystallizable substance, akin to Panum's septic poison. The conclusion is, that another function of the suprarenals is to remove or use up certain poisonous metabolites that accompany the worn-out pigments.

Summarizing the foregoing, therefore, it is concluded that the suprarenals are blood-glands having the function of removing effete pigments and effete proteids. When the organs in question are diseased, these products circulate in the blood, producing, on the one hand, pigmentation of the skin, on the other, the depressive effects of a septic poison.

As the suprarenals are not the only blood-glands, it does not follow that serious phenomena always result from their disease. Their duties may be performed by other organs having allied function.

A CONTRIBUTION TO THE ETIOLOGY OF CONGENITAL SYPHILIS.

IN addition to the intrinsic importance of the subject, the question of congenital or hereditary syphilis is one that possesses great interest to the student, because of the many uncertainties connected with it. Syphilographers are now very generally agreed that a syphilitic woman may beget a syphilitic child without infecting her husband, and some believe that a man who is a sufferer from the disease in its later stages may beget a syphilitic child while the mother escapes infection.

Although there is little doubt concerning the first of these points, there is, nevertheless, much dispute as to the time at which the child becomes infected. It was formerly held that a woman who did not acquire the disease before the seventh month of gestation would give birth to a healthy child. Chabalier has reported a case in which a woman became infected sixty-three days before the birth of a syphilitic child. But an instance is now related by Dr. F. Sorrentino, in *La Riforma Medica* of December 23, 1887, in which the date of infection was but fifty-two days before delivery.

A woman, twenty-six years of age, of sound general health, had been married at the age of twenty to a coffee-house keeper, by whom she had had two healthy children born at term. In May, 1886, her husband left her, when she was two months pregnant, and went to Marseilles on business. He returned home on November 14th, and had intercourse with his wife at that time, infecting her with a syphilis which he had contracted during his absence. Fifteen days after the primary sore was noticed an extensive roseola appeared, which was treated energetically by subcutaneous injections of mercuric chloride. The child was born on January 5th, fifty-two days after the mother's infection. It seemed at first to be healthy, but soon manifested the symptoms of hereditary syphilis. There was no sore about the lips, mouth, or pharynx to suggest the possibility of infection from the mother post-partum.

This case, if all sources of error can be excluded, would appear to demonstrate conclusively that a woman may give birth to a syphilitic child when her disease is contracted later than the seventh month of gestation.

THE PHYSIOLOGY OF INTESTINAL ABSORPTION.

The chief seat of absorption is in the small intestine. This is shown, not only by experiment, but by ordinary physiological and anatomical considerations. The immense convoluted surface exposed, the peculiar arrangement of the villi, capillary plexuses, and lacteals, all indicate that this tract is a specialized organ for the important object of absorption. It has always been admitted that osmosis, and, to a slight extent, filtration, were prominent factors in the mechanism of absorption. The products of digestion diffusing through the epithelial layer are taken up partly by the rich capillary plexus lying about the lacteals, and partly by the lacteals themselves. Naturally, the more diffusible substances, like mineral salts, sugar, and peptone, would be caught by the blood-vessels, while the fats would mostly pass through the mesh-work of capillaries to the lacteals.

The question, however, which has been hotly discussed by physiologists is, whether the epithelial cells lining the mucous membranes take any vital part in the process. Many observers have noted the fat particles in the bodies of these cells, and they have argued that the epithelial protoplasm took an active part in picking up these particles and conveying them through their substance to the reticular spaces beneath. In some animals ciliary processes exist which seem to have for their object the catching of the fat and drawing it into the body of the cell. Lannois found (*Archives de Physiologie*, 1882) that by the injection of alcohol into exposed loops of intestine the epithelial cells were destroyed, and absorption of oil, sugar, peptone, and mineral salts was delayed. The tendency of opinion of late has been in favor of the epithelial cell as an active factor in absorption, as it is in secretion.

M. Leubuscher (*Centralbl. f. Med. Wissensch.*, 1886) has made some experiments which seem to confirm this view. He found in isolated loops of intestine that the absorption of twenty-five to fifty per cent. solutions of salt took place just as rapidly as that of pure water, a phenomenon which would not take place if the law of diffusion were the sole factor in the process. The salts of soda were absorbed more rapidly than the salts of potash, and absorption was not hastened by the presence of bile—contrary to the general belief.

Gumelewski (*Pflüger's Archiv*, xxxiv., 1886) made a somewhat similar series of experiments, and reached much the same conclusion. Strong solutions of sulphate of soda increase the rapidity of absorption.

Thus, it seems that the process of absorption is as much a vital one as that of secretion, and that the epithelial cell not only aids the taking of fat into the blood, but also that of peptone (changing it to albumin), and of sugar and salts.

SEA-SICKNESS.

It is strange that during the ages in which man has suffered from sea-sickness no one has succeeded in finding a remedy for the malady, or, indeed, in solving satisfactorily the riddle of what it really is. Many, it is true, have been the explanations offered of the nature of the trouble, and specifics without number have been vaunted for the relief of its victims; but still those "who go down to the sea in ships" suffer just as did their fathers before them.

At a meeting of the Academy of Medicine of Paris, held on January 10, 1888, M. Ossian-Bonnet read an interesting paper on the subject, in which he settled, satisfactorily to himself at least, the question both of the pathogenesis and of the treatment of sea-sickness. He holds that the affection is purely nervous, and rejects the mechanical theories of its nature as unsound and leading to useless, or even harmful, methods of treatment. The one constant and essential symptom of naupathia, to use the author's favorite term, is not nausea, but vertigo. It is true that nausea and vomiting are exceedingly frequent accompaniments of the vertigo, yet they are not essential symptoms of sea-sickness, and may even be due to causes independent of those producing the latter. Thus, the vomiting which is so common during the first few days of a sea-voyage is as apt to be chargeable to indiscretions in eating and drinking just before sailing as to any motion of the vessel.

The chief cause of this vertigo is, the author believes, the motion of the ship. Yet not every motion is equally liable to cause the affection. Many persons are not sick during the rolling of the vessel, but suffer extremely when the ship begins to pitch. This is due to the giddiness caused by the sudden descent of the boat into the hollow of the wave. The same sensation is noticed by many persons while in an elevator that is descending rapidly; it is a feeling of "goneness" at the pit of the stomach, and this causes dizziness. The vertigo may also be excited by the apparent instability of surrounding objects, as sometimes is noticed on land in those riding in a merry-go-round. In short, the author's belief is that sea-sickness is a purely nervous affection, and that it is not to be explained by succussion of the brain or of the cephalo-rachidian fluid, by movements of the abdominal viscera, or by any other mechanical condition.

The treatment which M. Ossian-Bonnet found eminently successful was based upon this view as to the nervous pathogenesis of the trouble. In order to prevent the acute indigestion from which many suffer, he advises the use of some saline laxative every morning for two or three days preceding the setting sail. If there is vomiting after the voyage is begun, he recommends the sufferer to take half a glass of water after each attack. By this means *lavage* of the stomach is accomplished, and the act of vomiting is made less painful by reason of the water, which prevents the distressing contractions occurring when the organ is empty. But the remedy which the author has found to be a true curative agent, never having failed him in nearly sixty consecutive cases, is antipyrin. He was struck with the action of the drug in diminishing the excito-motor power of the cord, and was led to believe that it would be useful in controlling sea-sickness, which he had come to regard as a purely nervous affection. In order to test the remedy he made a voyage from Havre to Buenos Ayres and return, and the results of his experiments fully answered his expectations. In no case did the remedy fail, and in several instances of confirmed sea-sickness a cure was obtained after cocaine, morphine, atropine, and other drugs had given no relief. In most cases a dose of from twenty to twenty-five grains was sufficient, but in some it was necessary to repeat the dose, or to give the remedy in larger amounts. When vomiting was persistent it was necessary to give the first dose subcutaneously, a second dose, if one were needed, being administered by the mouth.

M. Ossian-Bonnet was fully persuaded that he had at last found a genuine remedy for this troublesome malady, but others before him have expressed themselves with equal confidence, and further trials of their supposed specifics have caused disappointment. It seems to be the fashion now to ascribe almost miraculous powers to antipyrin, but it is not a cure-all. Its power to relieve headache is undoubted, yet it often fails in this respect, even in cases which are supposed to be of just the kind to be most benefited by it. And doubtless the experience with the drug in sea-sickness will be of much the same character, it will relieve in many cases, and will fail to relieve in others. But even if it gives relief to but a few, it will be a boon to those, and would seem, at all events, to be worth trying.

THE MODERN PATHOLOGY AND TREATMENT OF CATARRHAL JAUNDICE.

THE pathology of catarrhal jaundice, first established by Budd, and more completely elucidated by Virchow, Vulpian, and Charcot, has long been considered one of the better-known problems of medical science. Many contributions in recent years, however, have been made, which tend to modify older views and to add preciseness to our knowledge of this interesting and by no means rare condition. The ordinarily accepted theory of catarrhal jaundice is that there occurs a duodenitis, or gastro-duodenitis, which extends into the ductus choledochus. The swelling and accumulation of mucus obstructs the exit of bile, which is thus dammed back and absorbed by the lymphatics.

The experiments of Oscar Wyss, in 1868, showed that in some cases at least (as in catarrhal jaundice from phosphorus poisoning) the catarrh of the ducts affected most their proximal portions, and that the obstruction occurred high up near their origin.

This view, that ordinarily the parts of origin of the bile-ducts are affected is, we believe, shared by Ebstein. The cause of the inflammation in the ducts, however, whatever its locality, has been thought to be extension from the duodenum, and Frerichs has reported clinical cases showing that in thirty-four out of forty-one cases the symptoms of gastro-duodenitis preceded those of jaundice.

M. Chauffard has made an ingenious argument to show that in many cases, at least, the sequel of events is first an accumulation of irritant products in the liver, causing an irritation and inflammation of the hepatic ducts, with intestinal inflammation following it. The investigations of Bouchard and his pupils, showing the important rôle played by toxic products of digestion and metabolism, lend support to Chauffard's view. The liver ordinarily destroys much of the toxic substances carried to it. But if the portal blood is overloaded with these, then there is "hepatic insufficiency," and a poisonous, irritating bile results.

The predisposing causes of catarrhal jaundice are exposure to cold, indigestion, abuse of alcohol, climatic and seasonal influences, and finally sometimes an epidemic infectious influence. The so-called epidemic jaundice has been recognized and described by Murchison, Kelsch, and many other writers. The observations of military surgeons, of which a number are cited by M. E. Parmentier in a critical review of this subject (*Gazette des Hôpitaux*, 1887, p. 1142), throw much light upon this form of the disorder. It seems to be proven that jaundice may be a specific infectious malady, developed in marshy regions, and in much the same surroundings as those that produce malaria or typhoid fever.

M. Kelsch is even of the opinion that all forms of ordinary catarrhal jaundice, sporadic or epidemic, are due to an infectious organism.

With regard to the symptomatology of jaundice, M. Parmentier calls attention to one interesting point, viz., that in those slight forms in which the bile pigments do not appear in the urine in appreciable quantity, the spectroscope furnishes a very delicate and accurate test. Besides this, M. Chauffard (*Revue de Méd.*, September, 1887) has established the fact that, in some cases at least, the urine is diminished in amount during the attack. By the tenth or twelfth day there is a crisis, with larger excretion of urine (3 litres), and a corresponding increase in urea (35 grammes).

Several German investigators have of late investigated the intestinal disturbances produced by the absence of bile from the intestine in jaundice. Müller, in particular, claims to have shown (*Zeitsch. f. klin. Med.*, xii., 1, 2) that in this condition there is an increase of undigested fat in the stools from 6.9 and 10.5 per cent., the normal amount, to 55.2 and 78.5 per cent. Strümpell claims that the clay color of the stools is due to the undigested fat, and that in jaundiced patients fed on fat-free food this peculiar color is not present. It is well known that the pancreatic duct may be also obstructed in jaundice; but Müller denies that this is the cause of the stearrhœa, and he cites cases in which this duct was obstructed, despite of which the stools contained less fat than is the case in catarrhal jaundice. The absence of the bile does not affect the dejection of starchy foods, but lessens slightly that of albuminoids.

Catarrhal jaundice has been divided into (1) the simple form, (2) the severe form, and (3) the malignant form. In the second type, the severity may be due to renal disease or some enfeeblement of the system, or to an excessive dose, perhaps, of the exciting poison. The malignant form often appears epidemically. There is, it is believed, an essential unity in the three types, and Kelsch concludes that they are all only different expressions of the same process, simple jaundice being only an abortive form of malignant jaundice, "just as gastric fever is only the expression of an attenuated typhoid fever."

In the treatment of catarrhal jaundice only one especially novel measure has of late been developed. This is the method of Krüll (*Berlin. klin. Woch.*, 1877, p. 159). It consists simply in the rectal injection daily of one to two litres of cold water, at first of a temperature of 12° R., then of 13° to 15° R. The fæces become colored on the second to fourth day, and general symptoms rapidly improve. Lowenthal, who employed this method in forty-one cases, speaks highly of it (*Berlin. klin. Woch.*, 1866, p. 159). He usually found that four injections were sufficient. Pregaldino, Kraus, and Eichhorst (cited by Parmentier) praise this plan of treatment, as do also Parmentier, Hayem, and Chauffard. The latter physician states that while ordinarily the stools are clay-colored for from four to six days, by the use of the injections the natural color is obtained in two days, and this return of color is accompanied by the critical polyuria and azoturia which we have already described.

THE QUESTION OF RHAMNUS.

The medical profession of Brooklyn is taking an active and justifiable interest in the subject of *rhamnus*. Dr. Squibb recently came out in favor, if we understand him correctly, of *Rhamnus frangula*, or alder buckthorn, as against *Rhamnus purshiana*, or California buckthorn (Cascara sagrada). Dr. Alexander Hutchins has expressed himself a champion of rhamnus, meaning, we infer, *R. frangula*, while Dr. T. M. Rochester begs to differ (*Brooklyn Medical Journal*). The question of the real therapeutical value of rhamnus, whether frangula, purshiana, or otherwise latinicized, may not seem of so profound importance as that of the political convulsions in Europe, but it may very seriously affect the personal comfort of many more or less dyspeptic citizens, and it quite deserves the serious consideration of practitioners.

The enterprise of manufacturing pharmacists has almost obscured the fact that there are at least five varieties of rhamnus. These are *R. frangula*, the bark of the old officinal alder buckthorn; the *R. catharticus*, or common buckthorn; the *R. infectorius*, a plant furnishing what is known as the French berries; the *R. purshiana*, or California buckthorn, better known as Cascara sagrada, or sacred berry; and the *R. ziziphus*, a shrub used in making jujube paste.

Of the above, only the *R. frangula* and *R. purshiana* are much in use at present, and, in particular, the exact value of the *R. purshiana* seems yet to be determined. The common experience of physicians, with regard to the *R. purshiana* is decidedly in its favor as a trustworthy laxative.

But Dr. Squibb seems to think that *R. frangula* is equally good. And Dr. Hutchins is very emphatic in its praises, for we take it to be the *R. frangula* that he recommends, though his language is a little obscure upon this point.

With regard, then, to *R. frangula*, Dr. Hutchins thinks that it has no place as a purgative, nor is it suited to cases of constipation due to organic disease. Its action is slow, and it has to be given for some time. It does, however, relieve chronic constipation, and it is an alterative in the sense that its continued use cures dyspeptic and constipated habit.

"In its use," says Dr. Hutchins, "two things are clear: first, that, ingested with food, it, at the same time, sooner or later, produces catharsis; if, then, the size of the dose, the frequency, one or both, be reduced, the effect can be maintained. The reduction of dose and frequency continued, a point is ultimately reached when a normal secretion is established, and beyond this rhamnus is an irritant; second, and a corollary to this, in health rhamnus is always an irritant. The rhamnus, therefore, within its own scope of action, regulates perverted functional secretion. If words have any meaning, rhamnus is alterative."

But though an alterative, and potent help in chronic functional dyspepsia, some interesting words of warning are given by the writer referred to, who says: "Except the patient be rich enough to afford continuous visitation, and pliant enough to submit to much mortification of the flesh, to say nothing of the world and the devil, a compact specimen of chronic dyspepsia is the worst kind of projectile dynamite to explode among the daisies that bedeck the busy doctor's path; and if he happen to pin his faith on rhamnus, he must not push it to illogical conclusions; for if his patient should happen, for instance, to have come to the knowledge of his stomach through the wearing experience of nervous strain and watchful, anxious, carping care, all the purshiana from the Sierras to the Golden Gate, and all the frangula from the gunpowder districts of Fatherland, would be inefficacious as an alterative, unless, perchance, with brain rested and pulse brightened by an Atlantic voyage or transcontinental trip, he shall himself pluck and peel and dry the small quill bark with his own right hand."

The mode of administration is to give drachm doses of an equal mixture of rhamnus, glycerine, syrup of ginger, and peppermint-water. This is taken after each meal.

Dr. T. M. Rochester, in the discussion that followed Dr. Hutchins' paper, said that he had been greatly disappointed in using the rhamnus, especially *R. purshiana*, the *R. frangula* he had found the most trustworthy of the two drugs.

PAY FOR THE TREATMENT OF PAUPERS.

If the State undertakes to take care of its paupers, it ought to pay reasonably for medical services, just as it should for services rendered by those who supply clothing, food, and shelter. This self-evident proposition has become modified in practice because, 1st, doctors have always shown a willingness to treat the poor for nothing; and, 2d, because where the poor are aggregated in large institutions the clinical experience afforded sometimes makes the position of medical attendant valuable. Neither of these facts, however, at all invalidates the proposition that the State should pay a reasonable sum for medical services.

In Ohio this question of compensation has come up in a practical shape. The law, we are told by the *Columbus Medical Journal*, in regard to compensation for professional services rendered to the poor (outside of the infirmaries) is in a very unsatisfactory state, as the amount to be paid seems to be left to the judgment, or caprice, of the township trustees.

Dr. R. Harvey Reed, of Mansfield, O., has brought suit to collect a bill for professional services rendered to paupers under care of township trustees.

The North Central Ohio Medical Society has adopted a resolution deploring and condemning the habit of township trustees in reducing medical bills to the lowest limit, and they recite the following: "*Whereas*, The township trustees, whose duty it is to care for these indigent citizens, do, in many townships, discourage and cripple the proper attention to said citizens, by either refusing to pay for medical attention to the same, or by reducing said medical bills to one-third or one-fourth of what would be considered a fair, reasonable amount, thereby either compelling physicians to take an unreasonably low compensation for their services, or resort to the expense of litigation to secure reasonable fees, at an additional expense to the township as well as to themselves——"

News of the Week.

UNHEALTHY ROYAL FAMILIES.—The London correspondent of The New York *Times* writes: "It is recalled now that Bismarck, who was already the chief man in Prussia, in 1858, strenuously opposed the marriage of the Crown Prince with the English Princess, saying that he was against any 'blood alliance with those scrofulous Guelphs.' The existing situation is a strange retributive comment on that utterance. Scrofula, or that worse allied disease with which so many royal strains of blood are contaminated, lays a heavy hand on the Hohenzollerns at San Remo and Berlin alike; but the taint has not come from England. A fact which has been privately known here for some months may now properly be mentioned. The present aged Dowager Empress of Germany, mother of the Emperor, has been a victim to hereditary scrofula, or a cognate malady, for many years. She got it from her mother, Marie Paulowna, who was a daughter of the crazy Czar Paul, one of the most thoroughly diseased men of his generation. All of Paul's daughters transmitted the taint to their descendants. One of them, Anne Paulowna, was mother of the present King of Holland, and the recent death of both his sons and the extinction of his male line are attributed to this. In the male Romanoff line the same malady caused the death of the Czarowitz, who was the elder brother of the present Czar, and now renders it very doubtful if the present youthful Czarowitz will ever reach manhood. In the Hohenzollern case, not only is the Emperor suffering from this hereditary taint, but his son William, who in a few weeks or months will be Emperor, is hereditarily deaf, and was born with a mere shapeless ball of flesh where the right hand ought to be. The Emperor's only sister is the Grand Duchess of Baden, and of her two sons one died last month, and the other is ill at Cannes and not expected to recover, both from scrofulous developments. The malady can, in truth, be traced all through the Almanack de Gotha among descendants of the Czar Paul. The disease only showed itself in the Empress Augusta when she had advanced in life, since when she has worn high dresses, and frequently was not visible to the public for months at a time." It may be recalled that one of Queen Victoria's sons had epileptic attacks and died of purpura hemorrhagica.

A SMALL MEDICAL STUDENT IN A BIG MEDICAL COLLEGE.—We have received from a medical student who has been attending a large medical college in this city, by no means meagrely endowed, a graphic description of his experiences in trying to get a medical education. The classes are enormous, the amphitheatre crowded, and the one that gets in first gets the best seat, consequently, there is a tremendous rush at the time of the lectures. Our correspondent, being a somewhat minute man, has been able generally only to get a back seat, and that in a more or less bruised condition. He states that he put his name down for a subject for dissection. He waited three months and his turn did not come, so he had to take out dissecting tickets in a homœopathic college not so well patronized. As for personal contact with the professors, he had had but one experience. Suffering from some gastric trouble, he made a call upon a member of the faculty, who received him courteously, prescribed some salts, and charged him five dollars.

OPHTHALMIC MEDICINE AND SURGERY holds its seventh international congress at Heidelberg from August 9th to 12th next.

PROFESSOR E. WAGNER, Professor of General Pathology and Pathological Anatomy in the University of Leipsic, who died at Leipsic on February 10th, had just completed the twenty-fifth year of his tenure of the chair of Pathology in the University there. In celebration of that event there has appeared, almost simultaneously with the announcement of his death, one of those volumes of collected memoirs with which it is customary in Germany for pupils to celebrate the jubilees of their esteemed masters. Professor Wagner's most noted work was his Handbook of General Pathology, first published in 1862. He was also editor of the *Archiv der Heilkunde*.

NOT FOR FREE TRADE IN SURGICAL INSTRUMENTS.—The New York Neurological Society, at its last regular meeting, voted unanimously not to indorse the resolutions of the Georgia State Medical Society, asking for the removal of all duties from surgical instruments and supplies. The ground taken was that the charges made against native instrument-makers were too intemperate and sweeping. Surgeons were better served by having their instrument-makers at hand rather than in Europe.

THE METROPOLITAN CLINIC, established at 445 West Forty-eighth Street, New York, for Surgery and Diseases of Women and Children, is opened Tuesday, Thursday, and Saturday, under the management of Dr. A. H. Goelet and Dr. W. B. Pritchard, both North Carolinians.—*North Carolina Medical Journal.*

HEART DISEASE AND MARRIAGE.—With regard to the question whether young girls affected with an organic lesion of the heart should be allowed to marry, Professor Jaccoud, in opposition to the views expressed by Professor Peter, believes that no absolute rule can be laid down. If the valvular lesion has never produced disturbance, then marriage is permissible. If symptoms of asystolia (especially in lesions of the mitral valve) have been observed, then there is considerable risk in marrying. Pregnancy would be very dangerous, on account of the pulmonary congestion which it would cause.—*British Medical Journal.*

Syrup of Tar and Apomorphine are highly recommended by Dr. William Murrill in the treatment of winter cough and chronic bronchitis.

State Medical Society Meetings.—The Arkansas State Medical Society will meet at Fort Smith on April 25th, 26th, and 27th.

The North Carolina State Medical Society will meet at Fayetteville on May 8th, 9th, and 10th.

A National Pharmacopœia to be published by the Government.—Mr. Randall has introduced into the House a bill appropriating $5,000 for the purpose of publishing a national pharmacopœia. It is to be edited by two officers of the Marine Hospital Service and two officers of the medical staff of the army and of the navy. The proposed work is to be held and accepted as the standard for the purveying, compounding, and dispensing of drugs or medicinal agents, and shall be taken as authority in the Treasury Department on all questions arising under the tariff laws of the United States with regard to the nomenclature, description, and purity of drugs or remedial agents, and shall further be received as evidence in the United States courts.

Lipanim is the name given by Dr. Von Mering to a mixture of oleic acid (6 parts) and olive-oil (100 parts), which he thinks answers as well as cod-liver oil.

Bequest to a Hospital.—By the will of the late Rev. Dr. Ryder the Chicago Hospital for Women and Children gets $10,000.

The Monopoly of Antipyrin (Dimethyloxyquinicin).—A Paris medical society, some of whose members are pharmacists, has been discussing the question of the sale of antipyrin, of which a German chemist, Dr. Knorr, has the monopoly. The conclusion adopted was, that as the substance dimethyl-oxiquinisin has been known since 1884—*i.e.*, since before the name "antipyrin" was registered in France—and as the process of its manufacture is perfectly familiar to chemists, it is open to pharmacists to dispense dimethyl-oxiquinisin prepared in France when "antipyrin" is prescribed. It was also remarked that the substance in question is exclusively used for medicinal purposes, and that according to French law medicines may not be patented.

America: Prehistoric and Present.—This subject, in its largest anthropological significance, will be discussed in a series of four sittings by the International Congress which meets at Berlin on October 2d next. The provisional committee consists of Drs. Virchow, Reiss, Bastian, von Richthofen, Voss, Olshausen, and Hellmann.

Succi, the Fasting Man, has begun a thirty-day fast at Florence, under the direction of Professor Luciani and the Medico-Physical Institute. M. Succi wants to persuade men of science that for periods hitherto considered impossible he can maintain the organism in health and activity without food.

A Truss for Straightening Crooked Noses is among the novelties in orthopedics. A mask of leather was at first devised for this purpose, but Mr. W. J. Walsam has lately (*The Lancet*) invented a felt skull-cap to which an apparatus is attached that produces any degree of lateral pressure on the deformed organ.

The Bill to Establish a National Bureau of Public Health is opposed by the Surgeon-General of the Marine Hospital Service, on the ground that things are well enough as they are, and that sanitary legislation and executive work can best be done by the Treasury Department. The friends of the bill, according to the *Sanitary News*, are the American Public Health Association, all the various medical societies, who realize that some more adequate system of national quarantine than we now have is to be required, and all the working sanitarians of the country.

Dr. Stonebridge has been sent to South America by the President to investigate yellow fever.

Penalty for Disseminating Infectious Diseases.—A bill has been introduced in the House of Representatives, by a Chicago member, which provides for a penalty to be inflicted on persons bringing infectious diseases into the United States, authorizes the supervising Surgeon-General of the Marine Hospital Service to build a laboratory, and repeals the act creating the National Board of Health. The bill is put forward, it is said, in order the more easily to kill the bill establishing a Bureau of Public Health.

Per Cent. of Graduates.—Our esteemed contemporary, *The American Lancet*, comments somewhat loftily upon the working of the Harvard Medical School, and thinks it gives "very poor teaching," because among 282 students only 76 were graduated, and of 87 applicants for degrees, 11 failed. By proper teaching, our contemporary thinks that no student is so dull or ignorant or generally unfit but that he can be made a doctor. This is an optimistic view of humanity surely. Some such plan may possibly be carried out in our contemporary's local institution (organized in 1885), since it graduates yearly almost forty per cent. of its matriculates. On the other hand, by the *Lancet's* rule, teaching is also a failure at Ann Arbor, which in 1884–85 graduated only 80 out of a class of 334, and next year 83 out of a class of 325, being a smaller percentage than that at Harvard. Does the *Lancet* wonder also why Ann Arbor does not increase in popularity among medical students?

A New Amylolytic Ferment.—Professor Ellenberger and Drs. Hofmeister and Goldschmidt report in the "Veterinary Archives" ("Archiv. f. Thierheilkunde," Bd. xiii., H. 3, *Medical Press*) a series of experiments on the amylolytic action of the saliva of the horse. These show that the natural mixed saliva has a much stronger amylolytic action than an artificially prepared mixture of the same saliva, and that the conversion of the starch into its soluble modifications—dextrine, sugar, and lactic acid—takes place within the stomach of the horse to a greater extent than can be accounted for by any mere fermentative properties of the saliva alone. Further experiments showed that oats themselves contain in or upon them an amylolytic ferment, which is an active factor in starch-digestion in the horse.

The Murderer of Preller.—We quite sympathize with the views of the *Medical Review* with regard to Maxwell, now the confessed murderer of Preller. His story of administering chloroform in order to pass a catheter seems plausible, and the idea that a little fellow five feet tall could have forcibly chloroformed and injected a hypodermic of morphine in a big man is improbable.

College Commencements.—The College of Physicians and Surgeons, of Chicago, recently graduated a class of forty-six.

The Medical College of Ohio, at its annual commencement, March 7th, conferred degrees upon sixty-nine graduates.

The Southern Medical College held its annual commencement on February 29th, and graduated thirty-two students.

The commencement exercises of the Louisville Medical College were held on February 17th. The degree of Doctor in Medicine was conferred on ninety-five graduates.

The Fort Wayne College of Medicine held its annual commencement on March 6th.

Rush Medical College has graduated a class of one hundred and thirty-two.

The University of Buffalo has graduated a class of forty-four, and Meharry Medical College (colored) a class of eighteen.

The Baltimore Medical College held its eighth annual commencement on March 9th.

The Medical Department of the University of Tennessee held its thirteenth annual commencement on February 22, 1888. The degree of Doctor of Medicine was conferred upon seventy-six graduates, and the degree of Doctor of Dentistry upon nine.

The Annual Dinner of the New York Polyclinic took place on the evening of March 20th, at Delmonico's. Besides the members of the Faculty there were present the Board of Trustees and several invited guests. Dr. James B. Hunter, the President of the Faculty, presided. Speeches were made by Mr. Coudert, President of the Board of Trustees, Commissioners Porter and Simmons, of the Charities and Correction, Dr. James B. Hunter, and Dr. John A. Wyeth, Dean of the Faculty. The latter gave a gratifying account of the growth of the school, especially that of the past year, stating that during the latter period three hundred and fifty-three medical practitioners had matriculated. The total attendance from November, 1882, to March 1, 1888, was 1,343, an average of more than 250 a year. In concluding his report, Dr. Wyeth urged that some of the clinical advantages of Bellevue be given to his school, claiming that the representatives of the College of Physicians and Surgeons were, by the remoteness of their new building, unable to avail themselves of their present appropriated share of appointments.

Aborting Syphilis.—Mr. Jonathan Hutchinson, in a recent paper, gives the weight of his authority to the view that syphilis can be in a measure aborted—*i.e.*, the secondary symptoms suppressed by the use of small doses of mercury. He gives half-grain doses of gray powder from three to six times daily.

The Coffin Trust.—We learn that even the coffin manufacturers have gotten up a trust, and have forced up the price of coffins over one hundred per cent.

The Kansas Medical Law Association is the name of an organization which proposes, by the aid of competent legal advice, to compare the laws of the States having medical practice acts, and, selecting the best parts of each, to frame an act which shall meet every requirement. Its work should receive support.

Bloomingdale Asylum will undoubtedly have to move, but it does not wish to be hurried, nor does it wish to be taxed. The counsel of the Society of the New York Hospital, in opposing the attempts to cut a street through the property, made the following statement with regard to the resources and work of the Society which owns the Asylum in question. Bloomingdale Asylum has, during its existence, received from the State $1,143,429.17; in bequests, $664,158.67; in donations, $282,752.14; making a total of about $2,000,000. The Society of the New York Hospital owns property, including the Hospital and Bloomingdale Asylum, assessed at about $5,355,000. This brings in an income of about $155,000. There is a bonded debt of $300,000. Bloomingdale Asylum is valued at $1,677,700.

Women Physicians have got ahead in Corea, if reports can be credited. A Mrs. Dr. Ellis is physician to the queen on the modest stipend of $18,000 a year, and another woman physician has been appointed assistant physician.

The Hoagland Laboratory in Brooklyn will, it is said, when completed, add another to the list of thoroughly equipped pathological and physiological laboratories in this country.

The Gothenburg Method of Dealing with the Alcohol Question has met with success in Norway and Sweden, and deserves to be known here. The essential features of this system, according to the *Medical and Surgical Reporter*, are that a responsible society purchases the right to sell liquors, and that the profits are used to pay interest upon the capital of the society, and the excess above this interest is devoted to public and charitable uses. A detail of the system, which is not without influence in diminishing the abuse of alcoholic beverages, consists in the fact that the keepers of drinking-places may not sell alcoholic beverages for their individual account; but may so sell non-alcoholic beverages and articles of food. This gives them a direct interest in diminishing the use of alcohol, and encouraging that of articles of food and drink which contain no alcohol. As a result of these measures, and of careful supervision by the government, the average consumption of strong drink in Norway, which was fifty-four litres *per capita* annually fifty years ago, is now only eight litres, or about one-seventh of the former figure.

Phthisis Conveyed to a Cat.—Dr. Léon Petit, at the Société de Médecine Pratique (*Journal de Médecine*, January 1, 1888), lately described a curious case of pulmonary tuberculosis transmitted to a cat by human sputa. M. Petit has already observed two cases of tuberculosis transmitted to dogs by human beings. The cat was in the habit of devouring the sputa of consumptive patients. This taste had become a passion; the animal followed the patients about, waiting for them to expectorate; it used to devour the tuberculous sputa which had served for microscopical examination in M. Petit's laboratory. After a time signs of phthisis appeared, the cat died, and autopsy showed tuberculosis.

St. Francis Hospital, New York.—The successful candidates fot vacancies on the House Staff were Drs. Leitner, Bennett and MacHale.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 16, 1888.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR

STATISTICS OF MORTALITY IN THE CITY OF NEW YORK,

in the form of a table, covering nine years since 1879, and being a continuation of statistics formerly arranged and published from 1804 to 1879, were presented to the Academy by DR. JOHN T. NAGLE. The gift was accepted with thanks.

THE PAUPER INSANE.

DR. SAMUEL SEXTON made some remarks on a bill before the State Legislature concerning the care of the pauper insane, and offered the following resolution, which was seconded and discussed by Dr. C. R. Agnew:

Resolved, That the New York Academy of Medicine heartily indorse the action of the management of the State Charities Aid Association, having in charge the bill providing for the better accommodation of pauper lunatics in this State, and recommend it to the favorable consideration of the Legislature.

The bill provided for State care of the insane of the several counties at an expense to the counties of $1.50 per head per week, the deficiency to be made up by the State. The asylums were to be distributed throughout the State by districts.

The resolution was adopted.

DR. AUGUST SEIBERT read a paper (see p. 317) on

CHOLERA INFANTUM AND THE WEATHER.

The paper was based on an analysis of all the cases of acute gastro-intestinal catarrh occurring in children under five years of age during his service at the German Dispensary, a period of ten years, extending from 1878 to 1888. These statistics were also shown to harmonize with those of the mortality from this disease during the same period as recorded at the Board of Health. The frequency and mortality of acute gastro-intestinal catarrh were compared with the exact meteorological phenomena of the different years, months, and days. In these experiments the author had been guided by experience gained during examinations into the causes of fibro-pneumonia, some years previously.

The total number of cases of acute gastro-intestinal catarrh in children under five years of age, treated at the German Dispensary during the ten years of his service, was 8,036. Charts were exhibited showing the number of cases occurring during the several months of the several years, the daily temperature-record, rainfall, and velocity of air-currents. The cases for each month during the ten years were also arranged separately, and compared with the meteorological phenomena.

It was found that very few cases occurred during November, December, January, February, March, and April; May had a few more; but during June, July, August, September, and October, this disease was very frequently met with. The difference between the two halves of the year was so great as to justify the use of the term summer complaint, or to show, at least, that some potent agent prevailed during the warm months to aid in the development of this malady. Of all the months of the year, the disease showed its greatest morbidity during July. For the ten years the number of cases occurring in July had been 2,443; August came next, with 1,524 cases, or one-third less than July; February, the coldest month, had the smallest number of cases, 117, during the ten years. Yet it was a noticeable fact that no month was entirely free from the disease. While July showed a greater number of cases than August, the temperature during these two months was nearly the same. The city mortality-statistics also showed during the ten July months 12,428 deaths from acute gastro-intestinal catarrh in children, while the number of deaths during the August months was only 6,205. The deaths in proportion to the number of cases was the same all the year round.

To show that high temperature alone was not the cause of the disease, it could be seen by the charts that in July, 1881, the mean temperature was 80° F., that of August, 82°, and that of September, 81°, yet the number of cases in July was 290, in August 223, and in September only 137. This same want of relation between height of temperature and number of cases of this disease during the summer months was also noticeable for other years and other summer months. It was also shown that one summer may be decidedly warmer than another, yet not bring forth a decidedly greater number of cases of summer complaint. One peculiar fact was observable, namely, that when the mean temperature of May was below 58° F. it brought forth no more cases than the winter months. Thus far it had been shown that the frequency of summer complaint, like its mortality, was, during the summer, independent of the rise and fall of the atmospheric temperature.

It was a general impression that during dry weather summer complaint was less common than during humid weather. To test the truth or falsity of this view, Dr. Seibert had obtained the daily barometric records for the ten years covered by his observations, and it was found that the number of cases and mortality of the disease had no constant relation to the dryness or humidity of the atmosphere, nor to the amount of rainfall, nor to the velocity of the air-currents.

There was also a prevalent opinion that heat had something to do with causing summer complaint, yet, on studying his charts in detail, it would be found that the summer days on which the temperature was highest showed no greater number of cases than those on which the temperature was moderate. Nor did he find the mortality greater during those months having the greater number of hot days. Thus it was shown that high temperature does not favor the production of cholera infantum more than medium warm weather.

Having gone thus far in his investigations, Dr. Seibert asked what are the special causes which give rise to this disease. He had shown that when the temperature rose to 60° F., it begins to prevail, and as to the cause of this he suggested that it is due to milk, which readily undergoes decomposition at 60° F. As it is milked in the heat of the day, brought to the city at night during the time the atmosphere is warm, and jostled over the streets, it is before its consumption exposed to all the conditions favoring decomposition. He would account for the lesser mortality in August, as compared with July, by the fact that in August public attention is fully awakened to the dangers of cholera infantum, and the people take precautions against its development.

DR. L. E. HOLT complimented Dr. Seibert on the excellent and laborious investigations he had made regarding the relations of summer complaint to the weather. We had learned much respecting any disease when it was shown us that our ideas of it were fallacious. Some statistics regarding this disease had been collected by a Liverpool physician, the period covering five years, and in one respect there was a significant harmony between them and those of Dr. Seibert. By those statistics it was seen that when the temperature approached very closely to 60° F., a further rise, bringing it even but a few tenths of a degree nearer the minimum established by the author, caused nearly three times as great mortality from acute gastro-intestinal catarrh. This, however, did not hold true of the month of September when compared with August, for the death-rate in September was more than August, notwithstanding the temperature-average was lower.

Dr. Holt was disposed to think we are yet including cases of different diseases under the term cholera infantum. He believed the main factors in the production of summer complaint are four: Heat, food, surrounding, constitution.

The most important single factor, acting directly or indirectly, is heat, but the more that are present the greater the frequency and the greater the mortality of the affection.

Dr. J. Lewis Smith fully agreed with Dr. Holt, that cases called cholera infantum are not always of the same disease. Even in the warmest weather he had certainly seen aggravations of the disease from sudden reduction in the temperature. So he believed that in the cold months we have a very different disease from that which prevails as acute gastro-intestinal catarrh in children during the warm months. We might be misled in estimating the comparative number of deaths in the different months, from the fact that those occurring in September and October were often in patients who had contracted the disease in July or August. He had not observed that difference between the mortality of July and of August spoken of by Dr. Seibert, and he believed the statistics of the Health Board showed nearly as large a mortality in August. He thought heat could be regarded as the cause of this complaint, but in what way it operates has not been definitely ascertained. Heat itself does not produce it, for, if it did, the disease would be as frequent in the country as in the city.

It may be the gaseous emanations and other atmospheric impurities present in warm weather develop it. But the opinion is gaining ground, and has already been accepted by those who have given most attention to this malady, that it is a microbic disease; that micro-organisms enter the stomach and intestines and are the active agent in causing summer complaint. As the comma bacillus causes Asiatic cholera by its own irritative qualities upon the intestinal tract, so may a certain micro-organism act in the causation of summer complaint.

Dr. Augustus Caillé said Dr. Seibert's investigations had not only shown that warm weather is a factor in the causation of this diarrhœal disease, but he had brought out certain points which had not been well understood. He took exception to the title cholera infantum. The author had considered spoiled milk as the chief cause of diarrhœa in children, and in that view Dr. Caillé concurred, yet he also thought that heat, inasmuch as it exerts a pernicious influence upon the human economy, paves the way for the reception by the system of the noxious material which is the immediate cause of summer diarrhœa. The reason why there are fewer cases in August is perhaps partly due to children being taken from the city and on excursions on the water.

Dr. A. Jacobus suggested, as one reason for the greater mortality from this disease in July, the fact that the children who take it in the earlier summer months have not yet regained their wonted strength after winter confinement.

The President said that in some cases of so-called cholera infantum there are the symptoms simply of a gastro-intestinal catarrh, but in others the secretions are less of a mucous than of a serous character, and they go hand in hand with early collapse, terminating fatally in a day or two, or perhaps running along four or five days. In those cases terminating early, the lesions may be trifling while the secretion has been immense, but the viscera generally are in a condition of granular degeneration. These latter cases are more apt to occur during the hotter weather, and the President believed heat had something to do with their causation. This view is perfectly reasonable, when we consider the influence of heat upon the nervous system and myosin. Cases of this class of cholera infantum are apt to occur in wealthy families as often as among the poor, while the more common form is rarely found among the well-to-do who keep the milk in refrigerators and follow instructions regarding the feeding of their children. The principal thing in keeping children healthy lies in how the food is selected, prepared, and given.

The President called attention to the fact that about ten years ago Clark Miller had stated that when the atmospheric temperature rose to 75° F. for six or seven days in succession cholera infantum would soon make its appearance.

Dr. Seibert said he did not include among his cases all of those of diarrhœal diseases; they were limited to acute gastro-intestinal catarrh. He had used the name cholera infantum because it took the least space on the invitation card. Whether the cases of acute gastro-intestinal catarrh, a disease commencing suddenly with vomiting and diarrhœa, are all due to but one cause or to different causes he was unable to say.

Regarding the mortality-statistics given, they could be relied upon as exact. Dr. Smith was not the only physician who had had the impression that the mortality in August was as great as in July, but the statistics at the Health Board and those of his own cases proved the error. Regarding the temperature of May and September, the average for the two months was nearly the same, but in September it often reaches a much higher point.

Dr. Seibert said one lesson to be learned from a study of these statistics is the importance of teaching the poor to take precautions against cholera infantum with the commencement of warm weather, and not to wait for hot weather before putting milk into the refrigerator.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY.

Stated Meeting, February 23, 1888.

A. R. Robinson, M.D., President, in the Chair.

Dr. Charles S. Wood read the paper of the evening (see page 320), entitled

SOME POINTS IN THE TREATMENT OF CHRONIC ALBUMINURIA, OR BRIGHT'S DISEASE.

The paper being open for discussion, **Dr. S. Baruch** expressed surprise that malaria was so prominent an etiological factor of Bright's disease. In a fifteen years' practice along the river-banks in a strictly malarial country he had seen hundreds of cases of fever, from May until November, but he stated that he had seen more cases of Bright's disease in New York in one year than in the fifteen years' experience in the South. Albuminuria was common during the paroxysms of fever, but chronic Bright's disease was extremely rare, not only in his experience, but in that of every physician practising in the same section. Dr. Baruch inquired if Dr. Wood expressed his own personal experience in stating that in the sections of the city where there is an increase of malaria there is an increase of albuminuria, and whether the diagnoses have been verified by autopsies. The cases described by Dr. Wood seem to have been of a rather mild form, lasting a long time, and many were cured, which is unusual with well-pronounced cases of Bright's disease.

With regard to treatment, Dr. Baruch is convinced that medicinal treatment is of very little value in Bright's disease; that hygienic measures, the ground of which is suggested by physiological laws, should be used. It is a well-known fact that highly nitrogenized foods increase tissue-metamorphosis, not only of the food which is ingested, but also of the nitrogeneous substances in the human body, and therefore, by the ingestion of this food we give the kidneys, which are the eliminators of the products of tissue-metamorphosis, a great deal of work to do; while, on the other hand, by the use of hydro-carbons we find that the tissue-waste is limited, and, therefore, the kidneys will have less work to do in throwing off this waste. Rest, a proper regulation of the diet, and abstention from active exercise form the most successful elements of treatment. The patient should have plenty of fresh air, but active exercise increases the metamorphosis of tissue, even in health. Leube, in the examination of large bodies of soldiers, found that a large number had albumin in the urine after the manœuvres. Therefore, by abstaining from active exercise, and by acting upon the skin, much more will be accomplished than by medicine.

With regard to the medicinal treatment, there is only one remedy in which Dr. Baruch has confidence, and to which the author of the paper referred with commendation, and that is nitro-glycerine. It relieves all the headaches and faintness, and it staves off the occurrence of cardiac hypertrophy. Dr. Baruch recalled a case of chronic nephritis, under treatment during the last two and a half years, which illustrates the effects of this treatment. Patient's urine was scant, although of a low specific gravity (1.007); it had an abundance of casts and kidney epithelium. Patient had been under this treatment, eating no meat until recently. Examination of his urine about a week ago revealed a mere trace of albumin, while the specific gravity and quantity were normal. Altogether, this is one of the most remarkable results after so serious a beginning.

While Dr. Willard Parker recommended bichloride of mercury, Dr. Baruch inferred that he also recommended the use of hygienic measures. If an organ be crippled it must be given rest, and that can be accomplished in Bright's disease by dieting the patient, excluding animal food entirely.

Dr. R. C. M. Page believed it impossible to cure chronic Bright's disease by medication, but there are a few medicines which are certainly invaluable for the relief of symptoms. For instance, nitro-glycerine sometimes relieves uræmic headache like magic. He usually gave one drop of a one per cent. solution, increased gradually up to five drops three times daily, and continued until the patient begins to have flushed face and to complain of laryngeal constriction.

Regarding uræmic dyspnœa, nothing acts so well usually as a hypodermatic injection of five or even ten minims of Magendie's solution of morphine. Chloroform by inhalation is the best remedy known for uræmic convulsions, while ether should never be administered. As to ether, the almost concurrent opinion is that it ought not to be used in any surgical operation where Bright's disease of the kidneys exists.

Pilocarpin has been recommended for the purpose of eliminating this so-called uræmic poison. The chief objections to this remedy are its depressing effect upon the heart, and sometimes it causes such a profuse salivary secretion that the patient almost strangles. His practice, for several years, has been to give pilocarpin in a solution of morphia, *e.g.*, one-eighth of a grain to ten minims of Magendie's solution. The morphine holds the heart up to its work, while the pilocarpin causes the patient to sweat profusely.

In a summary of one hundred and seventy-five cases Dr. Page has found that the old remedy, pulvis purgans, is the most trustworthy hydragogue cathartic, although the dose is large and unpleasant. Elaterium is more readily administered, but it is uncertain. He has never found any way of giving it hypodermically.

Mercuric chloride is without doubt a proper remedy in cases of Bright's disease, especially when depending on syphilis. But it is used indiscriminately. In the old New York Hospital it was the routine practice to give one-thirty-second of a grain of mercuric chloride in some bitter tonic. Its use should, perhaps, be restricted to those cases of cirrhotic disease depending upon syphilis.

Dr. P. C. Cole doubts the importance of malaria as a factor in Bright's disease. In his experience as an army surgeon, principally in Louisiana, where malarial fever was prevalent, Bright's disease was very rare. In Italy Bright's disease is practically unknown, and many parts of Italy are very malarious during a large portion of the year. Also in New Mexico, where ardent spirits are largely used, Bright's disease is unknown. If malaria were the predominating cause of Bright's disease, we should have more of it, and it would prevail in the malarial districts of Italy and other countries, which is not the case. With regard to treatment, while chronic Bright's disease, involving marked tissue-changes, must be regarded as incurable, much can be done to alleviate distressing symptoms in the later stages by the use of opiates. In the early stages, when small granular casts first make their appearance, great benefit is derived from counter-irritation by means of dry cups over the region of the kidneys every two or three days.

Dr. Robert Newman took exception to the general idea that remedies do no good in chronic Bright's disease. He narrated a case which was unquestionably Bright's disease, and which was cured by medical treatment. The diagnosis was verified by the visiting staff of the New York Hospital, during ten months of treatment there. Though it was expected that she would die, Dr. Newman afterward treated her for twenty-one years. At last she drank herself to death after acquiring a pension.

Dr. M. Blumenthal's experience in Bright's disease would not allow him to concur in the malarial origin of the disease; but that there is some ground for believing that malaria more often causes Bright's disease than we are generally willing to concede, is proven by the array of authorities quoted in the paper.

Dr. Blumenthal cited the case of a girl, aged ten or twelve, who was given up as hopeless, but, like Dr. Newman's case, she did not die, but lived to enjoy perfect health for many years. She died finally of another disease. As to the curability at all of chronic nephritis, that question is not yet ready for final decision. Physicians who have been in practice for a number of years have seen cases in which there was no possible mistake as to diagnosis, and in which, seemingly, there could not be much chance of error about the prognosis, where the patients did recover. As a rule, the most precocious children, the most intelligent and refined organisms, are those most frequently attacked with the disease, and who most readily succumb, while the rougher, coarser-grained constitutions seem to have greater powers of resistance and a firmer hold on life.

Dr. C. A. Leale believes that the original cause of chronic Bright's disease may be intermittent fever, and he had followed up such cases with this cause over a long series of years. Whatever induces frequent congestion of any of the internal organs might act as a provoking cause of a nephritis.

Dr. W. M. McLaury believes that malarial poison may enter into the clinical course of chronic nephritis as a special factor. He cited a typical case of albuminuria in which the urine was loaded with albumin; patient had general anasarca, and was unable to move about except with the greatest effort. Dr. Alonzo Clark saw this patient several times in the course of six weeks, but gave no hope of his recovery. The treatment in his case consisted mainly of mercuric bichloride, arsenic, and tincture of iron. He entirely recovered, so that there was no trace of albumin in his urine within six months after the beginning of this régime. The patient is still living, is forty-seven years of age, and it is twelve years since he came under treatment. Dr. McLaury mentioned two other cases of albuminuria with dropsy, in which nitro-glycerine was used with negative effects, except to clear up the dropsical effusion.

Dr. J. H. Fruitnight did not think that malarial poisoning was so prominent a cause in the production of chronic nephritis as was maintained by the author in his paper, yet he was positive that it did at times exist as an etiological factor. He briefly narrated two cases, one of which was seen in consultation by Dr. Fessenden Otis, which were obviously influenced by malarial poisoning. This patient was a young man who lived on Staten Island, sixteen years of age, and who suffered from malarial fever nearly all the time. Albuminuria, convulsions, and dropsy succeeded each other in the usual order.

Dr. Fruitnight thinks that the effects of medicinal measures in this affection are entirely problematical. The only rational method of treatment is that of abstention from activity, with the ingestion of a nitrogenous diet.

Dr. Henry L. Taylor asked Dr. Baruch whether the protection of the skin from sudden changes of tempera ture by the adoption of some such thing as the Jaeger underclothing would not help to protect the system against adverse conditions?

Dr. Baruch replied that it would most certainly, and that it is a very important measure.

Dr. S. H. Dessau said that the views expressed in Dr. Wood's paper confirmed him in the opinion he has lately entertained, that the large majority of cases of Bright's disease are dependent upon some obscure neurotic cause. In this way malarial poisoning may be explained as the cause of certain forms of chronic Bright's disease. In this way, also, are explained in great part, the beneficial effects of sedatives and the action of nitro-glycerine.

Dr. T. H. Burchard had seen cases of Bright's disease in undoubtedly malarious patients. Whether the malaria was the cause of the Bright's is another matter. Still, there are no pathological reasons why malaria, which certainly produces great constitutional changes, cannot produce changes in the kidney, just as well as in the spleen and other organs. During this summer, while in Europe, Dr. Burchard asked Sir William Gull, of London, his opinion of the etiology of cirrhotic kidneys. The laconic answer was, "Gout, syphilis, climatic changes, and renal plethora." He defined renal plethora as "that condition of chronic congestion of the internal organs which is so common in Englishmen after they have passed sixty years of age." He said, "As a nation we have, as you know, a seeming predisposition to the development of organic congestion of a chronic character. I believe that that condition is one of the special predisposing causes of renal metamorphosis. I have seen so many cases for which no other cause could be assigned that I have been compelled to regard this form of plethora in advanced life as one of the principal causes." Charcot, of Paris, stated the most exciting cause of chronic Bright's disease among the French to be the peculiar nervous excitability of the people. He is a great believer in the nervous origin of chronic Bright's. At Berne, Professor Dennie, who is highly respected in this department of professional labor, and who is in a position to see, probably, as large a representation of the different nationalities as any other man in Europe, said: "The more I have seen of Bright's disease, the more thoroughly I am convinced that it is dependent principally upon two causes. In the first place, upon a rheumatic or gouty, or syphilitic condition. I presume that one-third of the cases I see have either a latent or an acute rheumatic or gouty condition as a direct causative agent of the renal disease. The second class are cases in which we have chronic Bright's disease, resulting from an imperfectly cured acute attack." Upon inquiry if he had ever known malaria to be an exciting agent of Bright's disease, he said that he knew nothing about malaria, except as it exists in East Indians or in Americans: "We don't know what it is in Berne, I have seldom seen it here." Professor Dennie sees patients from every part of Continental Europe, while Sir William Gull sees English, Irish, Scotch, and Americans; Charcot, however, sees French, and some English and Americans. All are competent observers, and all gave as diverse opinions as were possible. Hence, we must conclude that cases are attributable to different causes; to gout in some cases, to syphilis, to the nervous element, and probably to malarious influences in other.

Dr. A. M. Jacobus did not think that malaria produced chronic Bright's disease, but that it had a very deleterious influence upon its course. While in the section of the South where Dr. Baruch had lived there was little chronic Bright's disease, it must be remembered that malaria as known in the city is quite a different thing from malaria in the country. People in large cities are very susceptible to climatic changes, and many of the cases of Bright's disease in New York City, Hoboken, and Jersey City have been largely due to malaria.

As a treatment, Dr. Jacobus thinks iron and quinine, in tonic doses, are indicated for albuminuria, while the patient should be restricted largely to a milk-diet. The case of a woman was cited, where there was no reason to suppose any renal difficulty. She went to Flushing and came down with intermittent fever. Then she came back to the city and developed albuminuria, followed by uræmic convulsions.

Dr. Baruch desired to be understood as not denying the possibility of Bright's disease being caused by malaria, because the fact that a careful observer like Dr. Wood had noticed it was sufficient evidence that his claim rests on a good foundation; besides, he has cited an array of authorities and statistics to fortify the theory. However, many cases are attributed to malaria, as Dr. Jacobus has said, because of an indistinct diagnosis. Dr. Baruch repeated the assertion, that since he had lived in New York he had heard more about malaria, and had seen less of it, than he had in the South.

The President (Dr. A. R. Robinson) agreed with Dr. Baruch almost entirely, except as regards the prognosis. In New York City it would be a very difficult thing to say whether in a given case of Bright's disease malaria was an etiological factor or not. For an accurate etiological study of Bright's disease, as regards this agent, a malarial district should be chosen, and comparisons made as regards frequency of the disease with a non-malarial district, the habits of the people being similar in both places. In examinations of a large number of cases every year, his attention had not been drawn to any relationship between malaria and Bright's disease, although the poison of malaria, no doubt, could so change, directly or indirectly, the blood-constitution, or the circulation in the kidneys, as to cause a nephritis. Recovery from acute parenchymatous nephritis frequently occurs, but I do not believe that this ever happens in cases of chronic interstitial nephritis.

Dr. Page added that he had never been able to trace a case of Bright's disease to malarial poisoning, but he did not doubt it might have more or less effect in bringing about the disease in individual cases. He further stated that in England, Ireland, and Scotland, where intermittent fever is unknown, Bright's disease is as common as in New York.

Dr. Burchard stated that he saw, while in Lucerne, a case that was singular in its way. A Swiss peasant was brought into the hospital one day, whose cadaverous appearance was marked and peculiar. He had every appearance of a man on the point of dissolution. He stated that a week before he had been feeling perfectly well. He then began to complain of rapidly increasing debility. On this account he came into the hospital. Upon examining him the house-physician in charge was unable to detect any organic change that would account for the man's excessive debility and his peculiar appearance, except extreme weakness in the heart's action.

Upon questioning the man on the amount of urine that he voided, it was found that he was making less than half a pint a day. Some urine passed at that visit was examined after standing a few minutes, and found to contain thirty to forty per cent. of albumin. Three days after this the albumin had increased very much, but no casts were found and no blood. At the end of a week after his admission to the hospital, Dr. Burchard again saw him, and the albumin was still increasing in his urine, although his general condition had somewhat improved. That night the man developed symptoms of cerebral œdema, and died the following morning. Dr. Burchard was present at the autopsy, and, very much to the surprise of every one who witnessed it, not the slightest change was found in the kidneys that would account for the albumin in the urine. Several physicians who saw the kidneys pronounced them absolutely healthy. The kidneys were anæmic—both cortical and pyramidal portions of normal consistency.

The question that was naturally excited by reason of this pathological discovery was, What caused the albumin in the urine? Certainly it was not dependent upon any disease in the kidneys that investigation could discover; and there were neither casts nor blood.

In closing the discussion Dr. Wood stated that the majority of the profession would not concur in regarding malaria as an etiological factor of chronic nephritis, but the authorities adduced were undisputed; for instance, Rosenstein, who is perhaps as thoroughly versed in kidney disease as any man in Europe. It is true that, during the war, chills and fever prevailed, while Bright's disease was not common; but many of those very men who returned, and established themselves in the city or country, did develop this so-called form of Bright's disease. With regard to the management of a case of chronic nephritis, Dr. Wood regards abstinence from exercise in the open air as most prejudicial to the patient's welfare. Dr. Wood protests against regarding the disease as incurable. A certain proportion of cases of Bright's disease are cured, or, at least, so alleviated that the patient may go on for years and enjoy comfort in life. Cases of cure are rare, but still there are sufficient to encourage us to persist in treatment.

Malaria, which produces chills and fevers in the country, has not the same tendency to produce Bright's disease that malaria has in towns and cities; and this form of the disease is amenable to treatment. In the early stages there are no casts, in contradistinction to the gouty form; and, although albumin persists, with low specific gravity, and the system is in a condition leading to Bright's disease, quite a number of these cases can be cured.

It is distinctly to be borne in mind that Bright's disease implies the presence of casts, irrespective of albuminuria.

In reply to Dr. Powell, Dr. Wood declared his belief that malarial poison does not effect any direct influence on the kidney in the production of Bright's disease, as, for instance, congestion, but that the nervous system becomes depressed by malarial influence, and progressive degeneration of renal tissues results.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE RADICAL CURE OF HYDROCELE—MEDICAL MEN AND THEIR MANNERS—CHEERFULNESS AS AFFECTING PROGNOSIS—A MEDICO-LEGAL CASE—THE WATER-SUPPLY OF LONDON—THE SKIN HOSPITAL SCANDAL—THE GALEN CLUB AND ITS PROMOTERS.

London, March 5, 1888.

At the last meeting of the Medical and Chirurgical Society only one paper was read, but the ensuing discussion filled up the remainder of the sitting. As, including the author of the paper, the speakers comprised surgical representatives from six of the London hospitals, the opinions expressed may be said to represent, not unfairly, present theory and practice on the subject in the London hospitals. The subject was an eminently practical one, viz., the radical cure of hydrocele. Mr. Henry Morris, Surgeon to the Middlesex Hospital, read a paper in which he reviewed various methods of treatment. He thought there was not much to choose, either as to duration of treatment or certainty of result, between injection on the one hand and incision or excision on the other. He believed there was no method yet devised which was not liable to occasional failure, and related two cases in which the hydrocele recurred after excision of the sac. Incision or excision was, however, to be preferred to injections whenever we were in doubt as to the precise nature or relations of the hydrocele, in some cases in which a hydrocele was complicated by hernia, when the hydrocele was caused by the presence of a foreign body in the tunica vaginalis, when the testes were diseased, or when a vaginal hydrocele was associated with an encysted hydrocele of the cord and a bubonocele on the same side (as in a case of his own). The President, Mr. Pollock, opened the discussion by narrating a case he had treated. The hydrocele was tapped and injected twice, but in vain. A silver wire was then passed through and kept in for three weeks, but also failed to prevent recurrence. The sac was then laid open and dressed with lint from the bottom, day by day, for a fortnight. Profuse suppuration ensued, but on allowing the wound to heal the hydrocele returned again. The patient declined any further treatment than simple tapping.

Sir Joseph Fayrer observed that hydrocele was both a commoner and graver affection in India than here. It was often the local expression of malaria, and nearly always the precursor of elephantiasis. He had seen cases in which the wall of the sac was half an inch thick and contained cartilage and bone. For such there was no treatment but excision. For hydroceles of moderate size he believed the best treatment was to inject two drachms of strong tincture of iodine. He had never seen recurrence after that method.

Mr. Willett showed a patient in whom a recurring hydrocele had been unsuccessfully treated by excision of a portion of the tunica vaginalis. The cavity was found obliterated by a buboid growth, from the meshes of which fluid escaped. An unsuccessful attempt was made to peel off this buboid tissue.

Mr. Bryant said he used as an injection equal parts of the tincture of iodine and liquor iodi into an emptied sac. He had had good success with this method. He had incised twice, and performed excision once. In all three cases recurrence followed, but they were all cured by subsequent iodine injection. He had employed injections of simple hot water with success, and recommended it in those cases where iodine injections had failed, and as a measure to be tried before incision. In the case of old hæmatoceles with thickened walls, and hydroceles with thick, viscid fluid, incision was required.

Mr. Harrison Cripps said he had experienced failures even when all the fluid had been withdrawn and pure tincture of iodine injected.

Mr. Treves said the method he now adopted was to open the tunica vaginalis and swab out the sac with crude carbolic acid. This destroyed the endothelium and set up suppuration.

Mr. Walsham thought the only really radical cure was to stuff the sac from the bottom and allow it to granulate up. That was too serious an operation in many cases, and for out-patient hospital practice he recommended simple tapping.

The manners of doctors with their patients vary very greatly. Some are extremely affable, some—well, somewhat the reverse. Some are very taciturn; others very voluble and full of details of treatment to be carried out by their patients. Whether justly or unjustly, it is said that one eminent and titled physician owes no inconsiderable share of his large and ever-increasing practice to his attention to detail in the instructions he gives his patients. Some doctors seem to take a delight in altering a patient's habits as far as possible; others will let him "gang his ain gait" as far as possible. That the latter is not inconsistent with the giving of a seasonable warning where required was made clear by an incident which came under my notice two or three days ago. Visiting an old friend at some distance, whom I had not seen for years, he related to me one of his medical experiences. He once had occasion to consult a hospital physician for some symptoms of circulatory derangement. He was an officer in a volunteer corps, and asked whether it was advisable that he should retire. The physician rejoined to the effect that he was old enough to know what he could do and what he could not, but that if he died suddenly, and he (the physician) were called as a witness at the inquest he should at any rate state that he had warned him. I need scarcely say the hint was taken, and probably proved all the more efficacious from the way in which it was conveyed. Some doctors are much more cheerful in their manners and countenances than others, and as cheerfulness is proverbially contagious, such probably encourage their patients more to struggle manfully against disease. Apart from personal cheeriness, too, cheerfulness in prognosis is not without its value both to patient and doctor. I may add, of two physicians at the same hospital, both of repute for their experience in cardiac affections, I have known one recommended for consultation in preference to the other on this very ground, viz., that he would take a more cheerful view of the case and not frighten the patient, and thus perhaps make him worse.

I briefly chronicled, some months ago, a case in the law-courts, in which a gentleman who had dined in a restaurant sued the restaurant-keeper for expenses which he had been obliged to incur through having (as he averred) swallowed a needle, which had, it was suggested, found its way into some chopped spinach in the process of preparation. The suit was unsuccessful, but a somewhat similar one has lately taken place with better success to the plaintiff. A baker sold a bun with a pin in it. It injured the throat of the purchaser, and finally had to be removed from her throat by a medical man. His fees amounted to thirty shillings, and the plaintiff sued for, and obtained, two pounds. I remember a medical friend once fancying he had got a pin lodged in his throat, from which he made vain efforts to dislodge it. He made his way to an eminent laryngologist, who soon showed him that his fancy was fact by withdrawing the pin with a pair of forceps from a fold of mucous membrane in the pharynx, where it had been arrested.

The Grand Junction Waterworks Company's Bill, for securing a supply of purer water to London, has been somewhat summarily thrown out by the House of Commons. It was not rejected on sanitary grounds, but on the plea, as alleged, that the new powers sought by the company would, if conferred, enable them to abstract from the Thames and its tributaries such a volume of water as would seriously and appreciably lessen the river, and even possibly cause a subsidence of the foundations of Windsor Castle. The latter was scouted as an absurd idea. I suspect that it was a feeling of mistrust toward the water company that led to the rejection of their bill. It was such an unprecedented procedure for a London water company to propose something to really benefit the consumers of what they are pleased to call pure water, that it is not much wonder that honorable members conjectured the presence of some sinister motive in the background.

The scandal at St. John's Hospital for Skin Diseases shows no sign of abatement. The Duke of Northumberland has withdrawn his patronage, but the managers persist in their refusal to grant an inquiry. Special hospitals seem particularly prone to become the arena of unseemly squabbles, possibly because, in some cases at least, they are, although nominally public institutions, really conducted in the interests of certain individuals. Whether this be the case at St. John's Hospital further investigations will doubtless disclose in due course.

The new medical club has not as yet made a very brilliant début. It is stated that the club will be under the control of the committee, and a "First Committee" is announced. Some secessions have, however, occurred from the latter, and whatever control the committee may ultimately obtain, it is pretty clear at present from what I hear, even adding the proverbial grain of salt, that this same committee will be very much under the control of the lay speculators who are launching the club. The Galen Club will probably share the fate of other medical clubs and find a premature grave.

ON TRACHOMA AMONG THE NEGROES IN THE UNITED STATES.

To the Editor of The Medical Record.

Sir: Your editorial in the issue of The Medical Record for the 10th inst., on "The Negro from a Medical Standpoint," was both interesting and timely, and, I hope, may be influential in calling forth more detailed and accurate statistics on the subject of race-influence in disease.

In regard to the general facts you mention respecting the greatly increased mortality among the negroes of the South since the war, there is unquestionably some showing of truth, though it must be remembered, in this connection, that we have no reliable vital statistics of the antebellum days with which to compare those we are getting now, and that isolated individual experience, while valuable, is by no means conclusive.

Undoubtedly there has been, since the war, a rapid thinning out of those of the negro race least fitted to survive in the struggle for an existence into which they were thrown without any preparation, but it by no means follows that the negro is going to die out in this country.

As a race, the negroes possess some qualities which will enable them to hold their own with the white man. Notwithstanding what has been said, I still think it is true that he can stand heat and malaria better than the white man, and his equable and cheerful temperament certainly stands him in good stead in warding off the worries and vexations of life, which sap the vitality as surely as disease. "Nervous prostration" has not yet established itself among them. It may also astonish many to learn that some competent observers, with a wide experience, are convinced that syphilis is much milder in its course, and much less deleterious in its effects in them than in their white brothers.

My own experience in syphilitic affections of the eye tends to confirm such an opinion. And to say that the negro had an immunity from certain diseases under a condition of slavery which he does not enjoy as a freeman seems to me like accepting the fact of revolutions going backward.

The negro in this country, from a medical stand-point, is as interesting a study as he is from a political or social point of view, and in assisting him in working out his problem (in which we are interested as well as he), we should, above all things, avoid too hasty generalizations from insufficient and unreliable data. You mentioned, in your editorial referred to, some recently published statistics of my own in regard to the comparative frequency of ear diseases in the two races, as they were observed at my clinic, and it is in the interest of a further scientific investigation of this question of race-influence in disease that I desire to again call the attention of the profession to some observations in the department of ophthalmology to which you did not allude, and which seem to me too remarkable to leave out of consideration in the study of this question.

In 1876, in a paper read before the Fifth International Ophthalmological Congress, held in New York, I called attention to the fact that, according to my observation, the negro enjoyed a comparative immunity from trachoma, or granulated lids. The observations of subsequent years have confirmed me in this belief, and I have published, at various times, statistics bearing on the point gathered at my clinical service at the Central Dispensary of this city, where the material is composed of whites and negroes in the proportion of two of the latter to one of the former. In 4,000 eye-cases available for statistical purposes, of which 2,600 were colored and 1,400 white, there were 70 cases of trachoma in the whites and but 2 among the negroes, and these were in mulattoes. An equal proportion in the two races would call for about one hundred and forty in the negroes. This discrepancy is due, I deem it, purely to race-influence, since the hygienic surroundings of the negro are certainly no better than those of the white contingent.

These are the observations of but one man, and at one clinic, it is true, but the information I get from other clinicians in other cities is corroborative in the main. One or two, however, claim to see trachoma in the negro very frequently, and others have reported isolated cases, and have thought thus to invalidate my conclusions. I have never contended that the negro *never* has trachoma. I only say that, according to my observation, which has been careful on this point, and has extended now through a number of years, he seems to enjoy remarkable immunity from it, and if anyone will furnish reliable statistics, as extensive as my own, showing that the negro does have trachoma as frequently as the white man, then I shall consider that we have either got hold of a peculiar race of negroes in Washington, or that there is something in the atmosphere of the national capital antagonistic to the development of the disease in that race. It is my firm belief at present, however, that it is a race-peculiarity, and, being so, throws a great deal of light on the much-vexed question as to the etiology of trachoma. It removes it from the category of purely local and contagious diseases, and places it among the dyscrasia. Were this the time and place, I could adduce other facts and advance other arguments in support of this proposition. My communication has, however, already overrun the limits I had fixed for it, and I will close it by asking those practising among a mixed population to make observations on this point, being careful, however, not to confound true trachoma and hypertrophied papillæ, and send them to me. They will be most thankfully received, and due credit will be given in a publication which will be made on the subject, probably in the near future.

I am, Mr. Editor, yours most sincerely,

Swan M. Burnett, M.D.

Washington, D. C., 1734 K Street, March 13, 1888.

INSUFFICIENCIES OF THE OCULAR MUSCLES.

To the Editor of The Medical Record.

Sir: In Dr. Loring's communication, March 10th, he modestly asserts: "It is very evident that Dr. Stevens has never read Donders." I have read this in Donders: "Strabismus is a deviation of the eyes in consequence of which the two yellow spots receive images from different objects. In strabismus the visual lines do not cross one another at the point it is desired to observe." Donders does not tell me that strabismus must of necessity present an appearance of deformity which one might stand off and observe. Whatever may be my familiarity with Donders, I have not offended by prostituting the words of the great oculist, who has written in honesty, by making them convey to the unwary a meaning which he never designed to express. Such an unworthy practice should awaken resentment from every right-minded member of the medical profession.

Dr. Loring says that in his case of strabismus, called improperly by him "insufficiency of the externi without strabismus," "Dr. Stevens forgets to state that the diplopia was produced under a red glass and a prism." I did not forget that, for there was no prism. The occasion for that prism arose twenty years after the examination was made. The double homonymous images were not made by a prism, and its introduction into the case at this late date, like the misfitting quotation from Donders, is calculated to deceive.

Dr. Loring accuses me of a want of acquaintance with the effect of a colored glass upon vision. It is true that I am not acquainted with any effect of a colored plane glass whereby, by placing it before an eye, diplopia of 30° is produced at twenty feet, which continues in all points of the field of vision and can only be abolished in the median line at a distance of eight inches from the eyes. I am acquainted with a great many cases of strabismus, some so extreme that Dr. Loring might see the squint, and others of less degree, in which the patients are unconscious of diplopia until the two images are colored differently. I do not hesitate to say that one who supposes that 30° diplopia is produced by a plane colored glass, is laboring under a profound misconception.

We are at liberty to assume that this strabismic case is a typical example of all the observations which Dr. Loring has made in respect to "insufficiency of the externi," since he now quotes his remark about non-strabismic eyes in which there is insufficiency of the externi, "which shows itself, the minute the colored glass is placed over one eye, by homonymous images;" and especially as he now introduces a hitherto "unpublished exploit" of much the same character as his other case of strabismus, and which he also calls a case of "insufficiency without strabismus." This being true, the doctor can assure himself that I have not written of the same grade of "insufficiency of the externi," under the title of non-strabismic insufficiencies, as that which has engaged his attention. In any systematic arrangement of his class of cases they would come where the definitions of Graefe, Donders, and others have properly placed them, in the category of strabismus.

Should this controversy be the occasion of calling the attention of the profession to the crudities of doctrine entertained by those who think that there are no more problems in respect to the ocular muscles, and that their "illustrious predecessors" have closed the doors against further inquiry; should it promote new interest respecting the conditions known as "insufficiencies," and suggest the value of a more systematic arrangement and more critical study of the anomalies of the ocular muscles, it will have accomplished, not what the originator desired, but a more honorable and worthy result. George T. Stevens.

33 West Thirty-third Street.

THE "ORAL WHIFF."

To the Editor of The Medical Record.

Sir: I was much interested in Dr. Cheesman's article on the "Oral Whiff" in The Medical Record for March 3d, having had the symptoms he describes since my sixteenth year.

I can hear the "whiff" when lying on the left side, with the mouth open, and it is audible to others after running or similar exercise; it is observable with erect posture also.

It used to be a source of great annoyance and anxiety, and, while studying medicine, of course led me to reckon a heart disease as *one* of my incurable maladies. So I was examined by the late Professor Jewell, of Chicago, in 1866, and a year or two after by Professor N. S. Davis, both of whom gave me a clean bill of health as to heart and lungs, to my most intense satisfaction. From that time, owing to my entire change of habits as to out-door life and exercise when I began to practise medicine, the symptom has gradually decreased, and for the past two years I seldom observe it, and when I do, it seems to accompany some indigestion.

As a boy I was sedentary in my habits, fond of reading, and averse to exercise. I also formed the habit of smoking at the age of fifteen, and have kept it up ever since (finding it an excellent aid to digestion, a reliable remedy for worry, and promoter of calm reflection). I have, however, always considered this dietetic "whiff" responsible for the pathological one.

The "whiff" was never accompanied by pain or shortness of breath. I could, and can now, run up two or three flights of stairs without puffing. It never occurred during inspiration, but was audible in expiration, "loudest at the commencement and fainter toward the close."

I have examined the leading authorities on the heart and other medical literature for some notice of this symptom, but the article referred to is the first I have met. Although watching for it in practice, I have never encountered it. E. S. Cleveland, M.D.

Burlington, Kan., March 18, 1888.

THE PATHOLOGICAL IMPORTANCE OF THE NOSE.

To the Editor of The Medical Record.

Sir: No. 898 of The Medical Record (January 21, 1888) reached me to-day, and I feel obliged to ask you a small space in this valuable journal, to make some remarks about your editorial, "The Nose, the Source of all our Woes." (P. 74.)

Firstly, it was not a Dr. Gacy (as you call him abusively) who reported the question of aprosexia at the Congress lately held at Wiesbaden, but Dr. Guye, professor of the diseases of the ear at the University of Amsterdam (Holland), whose disciple I had the honor to be.

Secondly, the name the author gave to this condition was not "aproxia," but "aprosexia," from προσέχειν τὸν νοῦν, which grammatically might be placed parallel to "aphasia," "alexia," "amnesia," etc.

Thirdly, I wished to protest against the ironical manner with which you communicated this to your readers; the cases related by Professor Guye, also in the "Nederlandsch Tydschrift voor Geneeskunde," 1887, ii., p. 381, ought rather to excite others to make further investigations about this important question, also in relation to the "surmenage scolaire." Professor Guye thinks probable that many cases of "céphalée des enfants," which Germain Sée, in the "Académie des Sciences à Paris," attributed to the "surmenage" were rather caused by nasal disturbance, obstruction of the sinus frontalis, etc; and I might add, that during the last month I have met in my practice with many such cases also (as was often proved "ex juvantibus") whereabout I hope later to find an occasion to write more.

I am, sir, yours truly,
W. B. VAN STAVEREN, M.D.

ROTTERDAM, February 27, 1888.

[We are happy to publish the communication of Dr. Van Staveren, and to assure him that we did not intend to speak with any uncalled-for levity regarding the subject of the nose, an organ for which, æsthetically and pathologically, we have a high respect.

There is, however, a tendency just now, among certain rhinological specialists, to put forward the nose into undue prominence as a pathological centre, to encourage lopping at the branches instead of digging at the roots. This tendency we deplore, and cannot promise always to speak of it with respect.—ED.]

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 11 to March 17, 1888.

STERNBERG, G. M., Major and Surgeon. Ordered to proceed to Brunswick, Ga., on official business, and upon completion of same will return to his proper station. S. O. 57, A. G. O., March 10, 1888.

CROSBY, WILLIAM D., First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, with permission to apply for an extension of one month, to take effect after being ordered to a new station. S. O. 60, A. G. O., March 14, 1888.

KEAN, JEFFERSON R., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Sill, Ind. Terr., and ordered for duty at Fort Robinson, Neb. S. O. 56, A. G. O., March 9, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 17, 1888.

RUSH, W. H., Passed Assistant Surgeon. Detached from Navy Yard, New York, and ordered to Naval Hospital, Philadelphia, Pa.

STEELE, J. M., Passed Assistant Surgeon. Detached from Naval Hospital, Philadelphia, and ordered to Coast Survey steamer Bache.

OBERLY, A. S., Medical Inspector. Detached from Navy Yard, Portsmouth, N. H., and wait orders.

DUBOIS, F. L., Surgeon. Ordered to the Navy Yard, Portsmouth, N. H.

KEENY, JAMES, Assistant Surgeon. Ordered to the receiving ship Minnesota.

DEANE, C. W., Passed Assistant Surgeon. Detached from Marine Rendezvous, San Francisco, and ordered to Coast Survey steamer McArthur.

AUZAL, E. W., Assistant Surgeon. Detached from Coast Survey steamer McArthur, and ordered to Marine Rendezvous, San Francisco.

BIDDLE, CLEMENT, Passed Assistant Surgeon. Ordered to Naval Academy, Annapolis, Md.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 17, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	2
Scarlet fever	146	29
Cerebro-spinal meningitis	3	3
Measles	48	6
Diphtheria	118	51
Small-pox	9	3
Yellow fever	0	0
Cholera	0	0

A DOCTOR BANISHED.—A Russian physician, Dr. Dreipelker, of St. Petersburg, has been banished because he sent a patient away from the Information Office insufficiently clad, and in very cold weather, without giving her any assistance. The patient, an old woman, died in consequence. The Information Office corresponds very nearly to the Bureau for Out-door Relief. The officer in charge directs applicants to various hospitals. Dr. Dreipelker had no means of relief at his office, and it is difficult to see how he was to blame.

THE SECRET OF DR. DARWIN'S PROFESSIONAL SUCCESS.—In the "Life of Charles Darwin," many references are made to his father, Dr. Darwin, a very successful practitioner, and, as his son says, "the wisest man he had ever known." Dr. Darwin "hated his profession," yet he achieved great success in it. The two great causes of his success were his capacity of inspiring confidence, and his patience and fertility of resource in devising schemes for promoting the comfort of sufferers.

LAPAROTOMY IN NEW YORK CITY AND IN NORTH CAROLINA.—These men, teaching in the great hospitals here, are great men and great teachers, and far be it from me to take one jot or tittle from their merited honor, but oh, how great are their opportunities! If a big operation is to be done in New York, the surgeon can familiarize himself with the parts by immediate dissection. He is supported by able counsel, aided by trained assistants, and last, but by no means least, he goes into the operation without feeling if his patient die he will be looked upon as a sort of semi-murderer; for, if an unfortunate result follow, it is quickly forgotten in the hurry and innumerable death-rate of the great city. But with us, how different! A great emergency arises—a serious operation must be done immediately, and at best one can rarely obtain more than one professional assistant. Ofttimes the assistant will be a common laborer, the best light obtainable a pine-torch or kerosene lamp minus a chimney, and with a paucity of instruments, because too poor to buy a complete outfit, the surgeon gropes his way through delicate tissues till the work is done and the life of his patient is saved. I recall to mind now a case of successful laparotomy done for gun-shot wound of the abdomen, and reported at the last meeting of our medical society, in which I am reliably informed the operator had only the assistance of a negro field-hand and worked solely by the light of a pine-torch. —*Correspondence of N. C. Med. Journal.*

The Medical Record

Vol. 33, No. 13 New York, March 31, 1888 Whole No. 908

Original Articles.

A YEAR'S WORK IN ABDOMINAL SURGERY, WITH A REPORT OF SEVENTY NINE LAPAROTOMIES DONE IN 1887.[1]

By W. GILL WYLIE, M.D.,

NEW YORK.

At the last annual meeting of this Society I reported one hundred and twenty-five laparotomies, fifty-five of which had been done in the year 1886. I wish to put on record all of my cases of abdominal section, with an accurate account of the results, and to show that since we have learned the importance of cleanliness, and how to attain it, very great progress has been made; and although opening the peritoneum should always be considered a serious undertaking, yet when carefully done it is not a very dangerous operation, and its field of usefulness can be greatly extended and many lives saved when all other means are of no avail.

I have now to report seventy-nine laparotomies done during the past year under the following heads.

Suprapubic Hysterectomies.—Eight cases, all for uterine fibromata. Seven recovered and one died. This one was complicated by syphilitic pyosalpinx.

Ovariotomies.—Sixteen were for large ovarian tumors. Fourteen recovered and one died. Death was due to an acute interstitial nephritis, starting up on a chronic diffuse nephritis, the former being caused by the ether.

Laparotomies for Removal of the Uterine Appendages.—Forty-one laparotomies were done. Forty recovered and one died. The autopsy showed chronic and beginning of acute interstitial nephritis.

Miscellaneous Laparotomies.—Fifteen were done. Nine recovered and six died. In many of these the operation was done as a last resort, and with little chance of success. Of the six that died, the first was for a large septic pelvic abscess, with the patient very weak from prolonged septic peritonitis. Two efforts had been made to reach the pus by the vagina, with very imperfect results. Patient died of shock.

The second was a case of abdominal pregnancy, done out of town, on a patient too weak from prolonged sepsis to be moved. She died of shock.

The third was an extreme case of ascites, complicated by a large umbilical hernia, which was on the point of suppurating. There was a cirrhosed liver and diseased kidneys. She died of exhaustion on the seventh day.

The fourth was a case of strangulated hernia in a very fat woman. There was stercoraceous vomiting, but her general condition was good. The mistake was made in giving ether. During the operation she vomited once, but the strangulated gut was relieved without difficulty, and the operation completed. She came out from ether, talked, and seemed in fair condition, but again vomited, choked, and died in a few minutes.

The fifth was the saddest of all. A fine, healthy woman had an abortion; on the third day puerperal sepsis developed. On the fourth day of the disease I was called in consultation. Intra-uterine douches had not been tried; they were given every hour through the night; her temperature fell from 104½ to normal the next morning.

The family physician hardly thought another consultation necessary, but in eight hours her temperature was 104°. I saw her and advised laparotomy, but it was deferred until her condition was hopeless; pulse, 150; temperature, 105½°. She was literally soaked with sepsis. The abdomen was opened, and more than a pint of pus was emptied at once. She rallied well, but it was too late.

In puerperal sepsis which threatens life, if washing out the uterus every hour with solution 1 to 60 carbolic acid does not control the temperature, and if no lymphangitis or phlebitis or septic abscess can be found in the broad ligaments to be opened and washed out, then laparotomy should be done at once.

The sixth was another case of a splendid woman lost by delay. The case had been seen by Dr. A. Jacobi and Dr. E. L. Keyes, and diagnosed as pyelonephritis, and operation advised. When I saw her she was in a very feeble state, due to septic perinephritic abscess. This I opened freely and drained. More than a pint of pus was evacuated, and the index finger came in contact with a distended kidney; this was punctured, and a large amount of pus escaped. A calculus could be felt, but the patient was too feeble to warrant any attempt at removal. She rallied well, and for a week improved, but soon began to fail. Nephrectomy was then done, but she died from exhaustion on the sixth day. An attempt was made to remove the stones through the old opening, but it could not be done.

This was my third case of nephrectomy; the other two are alive, and in good health. Except in a certain number of cases, such as septic perinephritic abscesses, I would always elect to remove the kidney by abdominal section. When diseased and requiring operation, it is nearly always enlarged, and when enlarged, is pushed forward. In my two first cases, one reported in my paper referred to, and the other—the fourth—in the table of miscellaneous, there was no shock, and the operation was no more difficult than the removal of any deep-seated abdominal tumor.

The Results of Operations for Removal of the Uterine Appendages for Disease.—Taking all the cases that I have operated upon for removal of the appendages, up to January 1, 1888, there are 115 in number with 6 deaths: In the first 25 there were 3 deaths; in the second 25 there were 2 deaths; in the third 25 there were no deaths; in the fourth 25 there were no deaths. And I had a run of 61 consecutive operations without a death.

It seems to me that we have proved that it is not a very dangerous operation, so far as loss of life is concerned. Now as to the results on the health and life of the patient afterward.

In pyosalpinx there is no reasonable doubt but that it is the only way that any real relief can be had in the great majority of cases, and that it actually saves lives. The number of women who have died from the extension of local peritonitis due to pyosalpinx is very much greater than is generally known.

In hydrosalpinx the operation is not so imperatively needed, but often nothing short of removal relieves the pain of hydrosalpinx. It is nearly always bilateral, and as one tube only usually lies low enough to be tapped by the vagina, this operation can and should be excluded.

---

[1] Read before the New York State Medical Society, February 7, 1888.

In catarrhal inflammation, where the tubes are occluded by adhesions it is only a question of time for disturbance to functions and fixation of the uterus by adhesions in the broad ligament to necessitate removal of the appendages to effect a cure. Where there is no occlusion of the tubes, except in rare cases of hydatids of the tubes they should not be removed unless disease of the ovaries or uterus makes it necessary to remove them.

Hæmatosalpinx, if uncomplicated by disease of the tubes or ovaries, may not require removal; but, as a rule, the hemorrhage is the result of disease, which necessitates operation.

In tubal pregnancy, if diagnosed, or if rupture takes place, removal is the best treatment. If tubal pregnancy is complicated by disease, hemorrhage, or inflammation, laparotomy is frequently the only means of saving life, and if uncomplicated, then the operation for removal is attended with very little danger, and makes it certain that no further complication will arise.

As to the removal of the appendages for the purposes of stopping the menstrual function. It is justifiable in many cases of fibromata of the uterus, for it will nearly always stop the further development of the fibromata. Not infrequently the severe pains supposed to be due to the fibroids will be found to be caused by associated pyosalpinx. Submucous fibromata are not always cured by removing the appendages, if these are diseased or adherent, and now and then a case of this kind will bleed and increase in size, although the ovaries and tubes have been carefully removed. I make it a rule to curette the lining membrane of the uterus in all such cases before resorting to the removal of the appendages.

I know of no other uterine disease than fibromata that justifies removal of the appendages when *normal*, except perhaps some case of endometritis that cannot be helped by any other known treatment. Uterine hemorrhage, when due to disease of the uterus, can be stopped by curetting, if properly done, with a good steel instrument, although the little copper instrument so highly recommended will often fail to remove the tissues necessary to stop hemorrhages.

Dysmenorrhœa is undoubtedly due to uterine disease, and in almost all cases can be readily cured by either dilatation or divulsion, etc.; and removal of the appendages, when healthy, should never be done for uncomplicated dysmenorrhœa.

Where there is atrophy and degeneration of the uterus, with perversion of all the functions, and where menstruation prostrates and makes life miserable, removal of the appendages may be justifiable when all other means have failed to give relief; but it is still doubtful whether the characteristic cystic ovaries nearly always found in such cases can be called *normal*. Many of these cases taken early can, by dilatation and other stimulating local treatment, and by proper attention to the general condition, be developed into strong and relatively healthy women; but when over thirty years of age, and bedridden, the operation for removal can do little harm, and certainly in some cases gives the only relief; but it rarely ever makes strong and vigorous women of them.

In epilepsy, or so-called hystero-epilepsy, the operation for the removal of the appendages may seem for a time to do good, but rarely effects a cure, and, in my experience, in three out of four cases it did no permanent good. In such cases, unless I can definitely make out objective signs of local disease of either the ovaries or tubes, I will not operate.

I can say the same for all mental diseases that seem to be connected with functional disturbance of the tubes and ovaries, that is, I will not operate unless I can diagnose by the touch actual disease of the tubes or the ovaries, indicated by adhesions, marked enlargement, or fixation. There can be no doubt but that in a certain number of cases the operation is followed by marked mental depression for a time, which condition would be pretty certain to intensify mental disease. Subinvolution of the uterus, after labor and abortion, is not infrequently associated with serious mental symptoms that can be relieved by treatment which restores the uterus to a normal state. But the fact of the generative functions being disturbed or being abnormal in mental disease, does not necessarily imply disease of these organs, or that the generative organs have caused the mental disease.

I have found, as the number of cases operated upon increases, that about three per cent. continue to menstruate after removal of the appendages, and I know of two cases where, after operation, menstruation ceased for a year, and then started up and has been regular ever since. A close investigation of these cases that continue to menstruate after complete removal of both ovaries and tubes has led me to conclude that this occurs in those where the adhesions are great, especially where the inflammation contracts and shortens the ovarian ligament, and makes it very difficult to remove the ovary and not leave more or less of it in the stump, or where the adhesions make it necessary to tear the ovary into pieces to get it out, usually a small part being left on the floor of the pelvis or on the broad ligament. I do not know of a case where the ovaries and tubes, being entirely free from adhesions, have been removed close to the uterus in which menstruation returned and remained regular.

I suppose if the tubes and ovaries were removed before puberty, that the effect would be great in changing the character and nature of the woman; but when removed after full development they do not appear to have any marked effect on her appearance, character, or temperament in any manner whatever.

The use of large saline enemata during the operation, to make up for loss of blood and prevent shock.—In my report last year I advocated the use of hot water, at 115° F., poured freely into the peritoneal cavity during operation to prevent shock. During the past year I had two cases of profuse bleeding during operation. In one, a case of hysterectomy for a large vascular fibromata, several large venous sinuses were torn in lifting out the tumor, and as it had a double source of blood supply—one from the uterus, the other from enormously distended vessels passing into the tumor from the omentum—at least three pints of blood were lost before both pedicles could be secured. Immediately an eight-ounce salt solution of beef peptones was injected into the rectum while I was operating, and the injections were repeated every twenty minutes till four were given. They were all retained. Although there was at first marked symptoms of shock, the patient quickly rallied, and three hours later all signs of shock had disappeared. The enemata were repeated at longer intervals, and she made a good recovery.

The object of the hot saline injections was not merely to stimulate reaction or to nourish the patient, but have the hot saline solution absorbed and take the place in the circulation of the volume of blood lost. It is surprising how much the rectum will absorb under such conditions. I have had the opportunity to test this treatment in two formidable cases, and *I now propose to give large eight- to ten-ounce hot saline enemata during and immediately after laparotomy or surgical operations, to prevent shock and take the place of transfusion whenever loss of blood indicates their use.*

SUMMARY OF STATISTICS.—Of the 204 laparotomies 110 were private cases with 12 deaths, but 6 of the 12 were in extreme cases under the head of miscellaneous. Taking ovariotomies, removal of appendages for disease, and hysterectomies, there were six deaths—five in the first 50, and only one in the second 50 cases.

In the 94 cases done in Bellevue Hospital there were nine deaths—seven in the first 44, and only two in the last 50 cases, and both of these had chronic Bright's disease, rendered active by the ether or operation. As no cases have been refused operation where there was the least chance of saving life, either in or out of the hospital, it is plain that our methods of operating have greatly improved.

TABLE I.—*Removal of the Uterine Appendages.*

No. of case.	Where operation performed.	Date.	Age.	Married or single.	No. of children.	No. of abortions.	No. of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
		1887.	Years.									
1	Hospital..	Jan. 24...	36	W.	2	..	....	Salpingitis and ovaritis.	Complete removal of appendages.	No.	Recovery......	Has had severe pain in back and left iliac region for four years, making her totally unfit for work; cystic ovaries and catarrhal salpingitis.
2	Hospital..	Jan. 31...	45	M.	1	1	....	Salpingitis, ovaritis..	Complete removal of appendages.	Yes.	Recovery......	History of peritonitis after miscarriage. Intestines very adherent to uterus and its appendages. Tubes occluded and much thickened, ovaries both very adherent.
3	Private...	Feb. 19...	35	M.	..	..	....	Salpingitis and ovaritis.	Complete removal of appendages.	No.	Recovered without bad symptom.	Had symptoms of repeated attacks of local peritonitis, and bed-ridden for three years.
4	Private...	Feb. 23..	26	M.	1	1	....	Cystic ovaries, salpingitis?	Complete removal of appendages.	No.	Recovered without bad symptom.	Both ovaries enlarged and prolapsed. Has always had dysmenorrhœa, which became worse after the birth of her child, so that she spends much time in bed.
5	Hospital..	Feb. 24.	35	W.	..	..	....	Uterine fibroids, pyosalpingitis.	Complete removal of appendages.	Yes.	Recovery.....	Small fibroids on left side, posterior and anterior walls. Right tube contained pus. Both ovaries and left tube inflamed.
6	Hospital..	Feb. 28...	24	M.	1	..	No.	Ovaritis and salpingitis.	Removal of appendages on left.	No.	Recovery	Left ovary cystic, size small orange; tube also enlarged and inflamed; right side normal.
7	Hospital..	March 5..	24	M.	..	..	...	Pyosalpingitis and ovaritis.	Complete removal of appendages.	Yes.	Recovered without trouble.	Both tubes enlarged, firmly adherent. Ovaries cystic, and rolled up in broad ligaments.
8	Hospital..	March 5..	29	M.	..	..	....	Salpingitis or disease of ovaries.	Complete removal of appendages.	No.	Recovered without bad symptom.	Small fibroid on uterus, and left ovary enlarged and very hard, having undergone fibroid degeneration. Intense local pain since miscarriage. Could not stand local treatment.
9	Hospital..	March 7..	32	W.	1	..	No.	Uterine fibroid......	Complete removal of appendages.	No.	Recovery.....	For several years suffered greatly with pains in pelvis and thighs, and profuse and irregular hemorrhage. Fibroid in posterior wall.
10	Private...	March 30.	23	M.	..	?	....	Pyosalpingitis and ovaritis.	Complete removal of appendages.	Yes.	Recovered....	Tubes occluded and strongly adherent with the ovaries and broad ligaments. Ovaries undergoing suppurative inflammation.
11	Hospital..	April 2...	20	M.	1	..	No.	Ovaritis and salpingitis.	Removal of left tube and ovary.	No.	Recovery.....	Severe pain in left iliac region, especially during menstruation. Left ovary bound to mesentery and had a small hæmatoma attached.
12	Private...	April 9...	37	M.	.	..	....	Fibroids............	Complete removal of appendages.	No.	Recovered; no trouble.	For three years has been very feeble on account of severe uterine hemorrhage. Curetting was tried.
13	Private...	April 13..	30	M.	2	?	....	Ovaritis............	Complete removal of appendages.	No.	Recovered; no trouble.	For past four years been in bed with symptoms of repeated attacks of local peritonitis. Under constant treatment. Uterus retroverted. Ovaries prolapsed, adherent, and enlarged.
14	Hospital..	April 16..	22	M.	4	..	No.	Ovaritis and salpingitis.	Complete removal of appendages.	Yes.	Recovery.....	After using vaginal injection, ten months ago, had symptoms of local peritonitis. Uterus bound down by adherent appendages. Left ovary cystic, tubes occluded.
15	Private...	April 30..	32	M.	..	..	....	Fibroid tumor of the uterus complicated by salpingitis and ovaritis.	Complete removal of appendages.	No.	Recovered; no trouble.	Fibroid size of orange in posterior wall of uterus. Uterus, tubes, and ovaries matted together in bottom of pelvis. Tubes distended with muco-pus. Ovaries cystic. Five years practically in bed and under constant treatment for pain. Severe hemorrhages for several months. Very feeble condition.
16	Private...	May 5....	..	M.	..	..	....	Pyosalpingitis and cystic degenerated ovaries.	Complete removal of appendages.	No.	Recovered; no trouble.	Tubes contain muco-pus, adherent and occluded; ovaries adherent, and had cystic degeneration. Had worn pessaries for retroversion, but without much relief. Several attacks of local peritonitis lately.
17	Hospital..	May 28...	30	M.	..	..	No.	Uterine fibromata and cystic ovary.	Complete removal of appendages.	No.	Recovery.....	Has had constant pain in left inguinal region for sixteen months; severer during menstruation. Has been in insane asylum for five months. Fibroids in anterior wall; right tube dilated, and ovary cystic.
18	Private...	May 30...	..	M.	2	?	....	Cystic ovaries.......	Complete removal of appendages.	No.	Recovered; no trouble.	Five years bed-ridden. Several months in a hospital; had cervix sewed up; had become an opium eater.
19	Private...	May 30...	19	S.	..	..	....	Hystero-epilepsy; small ovarian tumor.	Complete removal of appendages.	No.	Recovery.....	Ovarian tumor, size of orange, filled with dark, bloody fluid on right side. Left ovary much atrophied and hardened. Clear history of epileptiform convulsions monthly.
20	Private...	June 11...	40	M.	3	..	....	Uterine fibromata...	Complete removal of appendages.	No.	Recovery.....	Left tube much enlarged; ovary, size of egg; four small fibromata on fundus.
21	Hospital..	June 11...	26	M.	..	..	....	Ovaritis, salpingitis, and fibroid.	Complete removal of appendages.	Yes.	Recovery.....	Patient more or less unfit for work on account of pain in pelvis for eight years. Uterus seemed to be about three times normal size from fibroid. Appendages bound down by adhesions on both sides.
22	Private...	June 20...	29	M.	..	..	....	Enlarged sensitive ovaries.	Complete removal of appendages.	No.	Recovered; no trouble.	Elongated fibroid-degenerated ovaries. Severe dysmenorrhœa.
23	Private...	June 20...	30	M.	..	..	....	Salpingitis and ovaritis.	Complete removal of appendages.	No.	Recovered. .	Occluded adherent tubes and cystic ovaries.
24	Private...	June 25...	29	S.	..	..	...	Fibroid of uterus and ovarian neuralgia.	Complete removal of appendages.	No.	Recovered....	Uterus studded with small fibroids. Constant pain for years. Small fibroids on ovaries also.
25	Private...	June 30...	36	M.	2	2	....	Fibromata.........	Complete removal of appendages.	Yes.	Recovered....	Fibroid size of three and a half months' pregnancy. Enormous enlargement of veins of broad ligament. Violent hemorrhages, not controlled by curetting.
26	Hospital..	July 26...	26	S.	..	..	...	Ovaritis and salpingitis.	Complete removal of appendages.	No.	Recovery.. ..	Suffered for past twelve years with pains in right iliac region, which have been getting worse and unbearable, with menstruation. Both ovaries and tubes inflamed and bound down, especially on right side.
27	Private...	July 30...	28	M.	1	..	...	Peritoneal adhesions fixing uterus backward, obstructing rectum; ovaritis.	Laparotomy; separation of adhesions.	No.	Recovered....	Except for adhesions, appendages apparently normal. Partial intestinal obstruction; constant backache.
28	Private...	Sept. 14..	29	M.	1	..	....	Old peritoneal adhesions fixing uterus backward and obstructing rectum.	Separation uf adhesions, of appendages, and uterus.	Yes.	Recovered....	Appendages apparently about normal, except from adhesions.
29	Hospital..	Sept. 15..	23	M.	1	..	...	Ovaritis and pyosalpingitis.	Complete removal of appendages.	Yes.	Recovery.....	Has had hemorrhage for a year; two months ago had severe pain in left iliac region, and a few days later noticed a lump. Left tube and ovary contained about five ounces of pus. Sac of abscess was very adherent, especially to rectum. Right appendages also very adherent; abdomen washed out with water; temperature, 100°.
30	Private..	Sept. 18..	27	M.	2	..	....	Fibromata.........	Complete removal of appendages; curetting.	No.	Recovered....	Ovaries twice normal size and fibroid-degenerated, having several small fibroids dependent from them. Fibroma in left cornu of uterus, of size of orange, and several smaller ones in posterior wall.

TABLE I.—*Continued.*

No. of case.	Where operation performed.	Date.	Age.	Married or single.	No. of children.	No. of abortions.	No. of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
		1887.	Years.									
31	Hospital..	Oct. 1....	26	S.	..	..	....	Ovarian neuralgia...	Removal of left of appendages.	No.	Recovery.....	Ever since puberty has had more or less pain in left iliac region, which has become worse and worse, especially during menstruation. Pain incapacitates her for work. Left ovary much atrophied.
32	Hospital..	Oct. 8....	34	W.	3	..	....	Uterine fibroids.....	Complete removal of appendages.	No.	Recovery.....	Painful fibromata with uterine displacement, and hemorrhagia.
33	Hospital..	Oct. 8....	21	M.	1	..	...	Cystic ovaries.......	Complete removal of appendages.	No.	Recovery.....	Constant pain. Both ovaries atrophied and cystic.
34	Private...	Oct. 12...	29	M.	2	1	....	Salpingitis and enlarged cystic ovary right side.	Complete removal of right tube and ovary.	Yes.	Recovery.. ..	Left tube and ovary removed previously. Large tube occluded: cystic ovary size of orange, containing coffee-colored fluid.
35	Hospital..	Oct. 15...	39	M.	..	..	No.	Uterine fibroid; multiple.	Complete removal of appendages.	No.	Died.........	Multiple, irregular, and painful fibromata seven in number Autopsy showed no signs of sepsis or peritonitis. Kidneys in state of chronic interstitial nephritis. With six other cases was poisoned by sewer-gas after operation.
36	Private...	Oct. 23...	38	M.	3	6	....	Pyosalpingitis both sides.	Complete removal of appendages.	Yes.	Recovery.....	Both tubes much enlarged, one containing about two ounces of pus; ovaries much inflamed and cystic; many adhesions.
37	Private...	Nov. 1...	36	M.	.	..	....	Double pyosalpinx and ovaritis.	Complete removal with abscess.	Yes.	Recovery.....	Bed-ridden for several years. Seven attacks of peritonitis in two years. Abscess held fifteen ounces.
38	Private...	Nov. 23..	38	S.	..	..	.	Ovaritis. Left side hæmatocele.	Removal of left ovary and tube.	Yes.	Recovery.....	Constant pain left side. Unable to walk without increase of pain. Ovary size of a duck's egg.
39	Hospital..	Nov. 12..	32	W.	1	..	....	Cystic ovaritis.......	Complete removal of appendages.	No.	Recovered....	Constant pain.
40	Private...	Dec. 1....	25	M.	1	1	....	Double pyosalpinx: ovaritis; tubercular?	Complete removal of appendages.	Yes.	Recovered....	Tumor size of a large orange in the right broad ligament, and one the size of a lemon in the left. Large abscess, tubes large and cheesy.
41	Hospital..	Dec. 12...	46	M.	2	4	....	Atrophied and adherent ovary; uterine fibroma.	Complete removal of appendages.	Yes.	Recovered....	Repeated attacks of local peritonitis—constant pain.

TABLE II.—*Ovariotomies.*

No. of case.	Where operation performed.	Date.	Age.	Married or single.	No. of children.	No. of abortions.	No. of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
		1887.	Years.									
1	Hospital..	Jan. 22...	30	M.	..	1	....	Intra-ligamentous cyst?	Ovariotomy.	Yes.	Died on fourth day from suppression of urine.	Cyst size of cocoanut imbedded in broad ligament of right side. Autopsy revealed chronic and acute diffused nephritis and cirrhosed liver.
2	Private...	Jan. 26...	52	M.	1	..	....	Parovarian cyst.	Ovariotomy.	No.	Recovered; no temperature.	Parovarian cyst size of cocoanut was buried in right broad ligament.
3	Private...	Feb. 23...	26	M.	..	..	....	Ovarian tumor?	Removal of papillomatous fluid and material by laparotomy.	Yes.	Recovered; relieved and improved by drainage.	Greatly distended fluid from ascites due to bursting of papillomatous ovarian tumor. Omentum, intestines, etc., all covered with papilloma. Drained for six weeks.
4	Private...	March 17.	31	M.	..	..	....	Ovarian tumor; ascites.	Ovariotomy; removal of several gallons of fluid and myxomatous material.	Yes.	Recovered; much improved by permanent drainage.	Omentum, intestines greatly enlarged by hundreds of jelly-like masses. Myxomatous material.
5	Private...	March 21.	27	M.	..	..	...	Ovarian tumor size of full-term pregnancy.	Ovariotomy; both ovaries.	Yes.	Recovered; hemorrhage.	Tumor was removed without difficulty. Drainage-tube showed hemorrhage three hours after operation. Patient collapsed and pulseless. Abdomen opened and quarts of clots turned out. Pedicle needle had split a vessel; re-tied. Patient made good recovery.
6	Private...	April 27 ..	21	M.	1	..	....	Ovaritis?	Ovariotomy; typical parovarian tumor.	No.	Recovered; no temperature.	Local peritonitis around a parovarian cyst size of duck's egg; had to remove tube and ovary with it.
7	Hospital..	May 10...	27	S.	..	..	....	Osteo-sarcoma attached to sacrum size of large child's head fixed in pelvis.	Ovariotomy; solid tumor; sarcoma?	Yes.	Recovered; no temperature.	Diagnosed by several as osteo-sarcoma and incurable. Pelvis filled by fixed *very hard* solid tumor. With abdomen open, very difficult to dislodge; the pedicle not larger than thumb. No adhesion, only wedged in the pelvis. Ten months after operation no signs of return.
8	Private...	May 21...	21	S.	..	..	...	Two elastic tumors—one on either side of pelvis.	Ovariotomy, complicated by pregnancy, fourth month.	No.	Recovered; without temperature: pregnancy not disturbed.	Ovarian tumor size of child's head. Uterus distended by pregnancy, fourth month.
9	Private...	May 30...	19	S.	..	..	....	Small ovarian tumor, complicated by hystero-epilepsy.	Ovariotomy, both sides.	No.	Recovered; without temperature.	Clear history of epileptiform convulsions monthly. Ovarian tumor size of orange made out.
10	Private...	July 20...	48	M.	3	..	....	Multilocular ovarian tumor.	Ovariotomy, both sides.	No.	Recovered; no temperature.	Simple multilocular cyst, twenty-five pounds; some omental adhesions.
11	Private...	Sept. 21..	33	M.	1	..	....	Ovarian tumor.	Ovariotomy; papillomatous sac had bursted; both ovaries removed.	Yes.	Recovered.	Papillomatous growth had burst the sac and caused peritonitis and very extensive adhesions.
12	Private...	Sept. 22..	57	M.	2	..	....	Ovarian tumor.	Ovariotomy, right side.	No.	Recovered; without temperature.	Simple multilocular cyst, twenty pounds. Some omental adhesions.

TABLE II.—*Continued.*

No. of case.	Where operation performed.	Date.	Age.	Married or single.	No. of children.	No. of abortions.	No. of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
		1887.	Years.									
13	Hospital..	Oct. 1....	43	S.	..	..	....	Ovarian cyst.	Ovariotomy, both ovaries.	Yes.	Recovered; temperature, 104°.	Simple ovarian tumor, ten pounds. Both ovaries cystic. High temperature due to sewer-gas poisoning. Several others affected by it.
14	Private...	Oct. 17...	28	M.	..	..	....	Fibroma? Dermoid cyst?	Ovariotomy, both sides.	No.	Recovered; no temperature.	Case long standing. Much local pain. Dermoid both sides—one size of cocoanut. Hair, bones, etc.
15	Private...	Oct. 27...	40	M.	..	..	....	Dermoid cyst? Fibroma?	Ovariotomy, both sides.	Yes.	Recovered; slight temperature.	Twelve years' standing. Diagnosed as fibroma. Dermoid both sides—one fifteen pounds. Hair, bones, etc. Pyosalpinx both sides.
16	Hospital..	Nov. 28...	30	S.	..	..	....	Dermoid cyst; ascites.	Ovariotomy.	Yes.	Recovered; highest temperature, 101½°.	Leg œdematous. Several quarts of ascitic fluid removed. Dermoid cyst size of an orange, hard and rough; long pedicle. Hair, bone, etc.
17	Private...	Dec. 29...	23	S.	..	..	....	Parovarian cyst.	Ovariotomy, both sides.	No.	Recovered.	Bedridden for several years. Intense local pain. Cyst size of a large orange.

TABLE III.—*Suprapubic Hysterectomies.*

No. of case.	Where operation performed.	Date.	Age.	Married or single.	No. of children.	No. of abortions.	No. of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
		1887.	Years.									
1	Hospital..	Jan. 12...	38	M.	..	..	....	Painful uterine fibroma.	Hysterectomy; suprapubic; pedicle extra peritoneal.	No.	Recovered; highest temperature, 101°.	Local pain and hemorrhage. Solid tumor filling pelvis and abdomen above umbilicus. Large fibroma, involving uterus, twenty pounds.
2	Hospital.	March 19.	28	M.	1	..	....	Uterine fibromata.	Suprapubic myomotomy; hysterectomy: pedicle extra peritoneal.	No.	Recovered; highest temperature, 100.5°.	Abdomen distended by a large vascular fibroma, twenty-three pounds. Severe hemorrhage and local pain. Immense veins attach the tumor to omentum. Pedicle involves right cornua of uterus. Ligated with silk and sewed in abdominal wound.
3	Private...	May 26...	28	S.	..	..	....	Multiple fibromata.	Suprapubic hysterectomy; enucleation of fibroma; pedicle extra-peritoneal.	No.	Recovered; no temperature.	Two tumors size of man's head, and third size of fist below vaginal junction. Broad ligaments and large tumors cut away. Small tumor enucleated. Patient size of full-term pregnancy before operation.
4	Private...	June 6...	35	M.	..	1	....	Fibroma size of a child's head. Old salpingitis syphilitic.	Suprapubic hysterectomy; pedicle extra peritoneal.	No.	Died fourth day of sepsis.	Fibroid size of head of six-year-old child. Tubes and ovaries imbedded in side of tumor. Pyosalpinx. Dense adhesions. Pedicle through the tubes. Patient feeble. Died fourth day, with high temperature. No distention or sign of peritonitis.
5	Hospital..	June 6...	37	M.	..	..	....	Uterine fibroma; rapid growth.	Suprapubic hysterectomy; pedicle secured extra peritoneal.	No.	Recovered; highest temperature, 101°.	In six months tumor grew as large as eight months' pregnancy. Dragging pains. Fifteen vascular fibroma were removed without difficulty.
6	Private...	Oct. 13...	54	S.	..	..	....	Uterine fibromata. Cystic degeneration.	Suprapubic hysterectomy; pedicle secured extra peritoneal.	No.	Recovered; no temperature.	Tumor for several years. Since menopause, two years ago, it has rapidly increased in size. Fibroma twenty pounds, involving whole uterus. Removed in centre was a cyst of a pint of clear straw-colored fluid.
7	Hospital..	Oct. 15...	34	S.	..	..	....	Uterine fibroma.	Suprapubic hysterectomy: pedicle secured extra peritoneal.	Yes.	Recovered; highest temperature, 101.2°.	Abdomen as large as eight months' pregnancy. Severe uterine hemorrhage. Much local pain. Large, very vascular, lobulated fibroma; eighteen pounds. Extensive adhesion. Large sinus. Great loss of blood. Hot saline rectal enemata during and after operation every twenty minutes. Twenty ounces or more absorbed and shock prevented.

TABLE IV.—*Laparotomies—Miscellaneous.*

No. of case.	Where operation performed.	Date.	Age.	Married or single.	No. of children.	No. of abortions.	No. of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
		1887.	Years.									
1	Private...	Jan. 6......	44	M.	1	..	..	Small ventral hernia one year after simple ovariotomy.	Laparotomy for cure of ventral hernia.	No.	Recovered. Without temperature.	No drainage-tube. Patient very fat, and had a severe cough soon after the ovariotomy.
2	Private...	Jan. 16.....	37	M.	..	..	..	Large septic pelvic abscess filled left side of pelvis.	Laparotomy; emptying and draining abscess.	Yes.	Died in twenty-six hours of shock and sepsis.	Abscess in left side of pelvis, involving the tube, ovary, rectum, and side of uterus. Patient had septic peritonitis at the time of operation.
3	Private...	Feb. 10.....	32	M.	1	..	..	Abdominal pregnancy; child had been killed by hypodermics of morphia at seven and a half months; septic for several weeks.	Laparotomy; fœtus. placenta, and several quarts of decomposing fluid removed.	Yes.	Died in thirty-six hours of shock and sepsis.	Patient weak from sepsis of several weeks' duration. Greatly distended. No loss of blood during the operation. Sponges left in cavity by mistake.

TABLE IV.—*Continued.*

No. of case.	Where operation performed.	Date.	Age.	Married or single.	No. of children.	No. of abortions.	No. of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
		1887.	Years.									
4	Private...	March 10...	35	?	..	..	..	Enlarged and displaced kidney; pyelo-nephritis; septic attacks; renal calculus.	Nephrectomy..	Yes.	Recovered; no shock; highest temperature, 101°.	Imbedded in the calicis was an irregular, mixed, hard stone, 100 grains. Chronic diffuse and acute nephritis; pyelitis. Patient, one year after, perfectly well.
5	Private...	March 17...	..	M.	..	..	..	Ascites from myxoma; peritonitis.	Laparotomy and permanent drainage for several weeks.	Yes.	Recovered; no temperature.	Several months before ovariotomy had been done. One cyst had burst, and myxomatous matter escaped in abdomen.
6	Private...	March 21...	..	M.	..	..	..	Collapse from hemorrhage three and a half hours after ovariotomy.	Laparotomy for hemorrhage from stump after ovariotomy.	Yes.	Recovered....	Not less than two quarts of clots and serum were turned out of the abdomen. The pedicle-needle had split a vein in the stump; when held up it did not bleed. Retied. Hot saline douches were used to prevent death from shock.
7	Private...	March 28...	..	M.	..	.	..	Strangulated umbilical hernia.	Herniotomy for strangulated umbilical hernia.	No.	Died one hour after operation; vomited matter in trachea.	Very fat woman. Operation completed. Patient revived from ether and choked to death on stercoraceous matter.
8	Private...	April 30....	..	M.	1	3	..	Suppurative puerperal peritonitis; sepsis.	Laparotomy; emptying more than a pint of pus, and washing and draining peritoneum.	Yes.	Died of shock and sepsis in twenty hours.	Septic peritonitis of several days. Temperature, 105⅗° at the time of operation. Inter-uterine injections failed. Laparotomy deferred. Sepsis extreme.
9	Hospital..	May 12.....	51	M.	..	1	..	Chronic pelvic peritonitis; partial intestinal obstruction.	Laparotomy; breaking up adhesions.	No.	Recovered....	Pelvic pains and intestinal obstruction relieved.
10	Hospital..	May 19.....	50	M.	14	..	..	Carcinoma of liver?..	Exploratory laparotomy.	No.	Recovered; no bad results from operation.	Cancer of liver and gall bladder.
11	Private...	May 21.....	34	M.	..	..	..	Abdominal dropsy and large ventral hernia; Bright's disease.	Laparotomy; removal of fluid; closing hernia; drainage.	Yes.	Died on fifth day; uræmia; suppression.	Contracted liver—size of hand. Ether caused acute congestion of kidneys.
12	Private...	July 1......	..	M.	..	..	..	Ascites; myxoma; peritonitis.	Laparotomy; permanent drainage.	Yes.	Recovered; relieved by drainage.	Second time the abdomen filled with fluid. Every organ has myxoma growing on it. Omentum a large solid mass.
13	Private...	Sept. 4.....	50	M.	1	2	..	Sarcoma?........ ..	Exploratory incision.	No.	Recovered; no bad effects from operation.	Sarcoma involved uterus and broad ligaments and intestines. Wound closed.
14	Private...	Dec. 17.....	28	M.	2	?	1	Renal calculi; pyelonephritis; perinephritic abscess; septicæmia.	Laparotomy; nephrectomy.	Yes.	Died in five days of sepsis and exhaustion.	Three weeks before had opened a large septic perinephritic abscess. Kidney enlarged; calicis filled with three large stones, 125 grains. Patient very weak from sepsis.
15	Private...	Dec. 21.....	23	M.	1	..	..	Necrosis of pelvic bones.	Exploratory incision.	No.	Recovered; no bad effects from operation.	No pelvic abscess found. Deformed pelvic bones and old periostitis. Wound closed.
16	Private...	Dec. 31.....	37	M.[1]	..	..	..	Perityphlitic abscess.	Incision and drainage; pint of fetid pus.	Yes.	Recovered without bad symptoms.	Local peritonitis and partial intestinal obstruction for six days. At the time of operation no temperature, good pulse; bowels moved naturally. Under ether the tumor was felt. Nucleus came away the second week. Recovery complete.

PROGRESSIVE PERNICIOUS ANÆMIA: TWO CASES WITH ONE POST-MORTEM EXAMINATION.[2]

By THOMAS E. SATTERTHWAITE, M.D.,

NEW YORK.

PROGRESSIVE pernicious anæmia is a rare but very dangerous form of blood disease, obscure in its origin, somewhat difficult of diagnosis, and seldom benefited by treatment. Developing in the most insidious manner, it progresses slowly but surely toward the fatal termination. Its main characteristics may be summed up as follows: The blood exhibits an extraordinary reduction in the number of the red corpuscles, which are also altered in shape and in their constituent elements, while the plasma is unnaturally fluid and coagulation does not occur, or is very imperfect. Hemorrhages also are frequent and from various parts of the body. A third characteristic of the disease is slight fever, of an irregularly intermittent type. But, with the gradual failure of the bodily powers, there is seldom any apparent loss of adipose tissue. Finally, the patient is inclined to be apathetic during the whole course of the affection, making few complaints of any personal suffering, and is often quite indifferent to things transpiring about him.

It seems to be clear that pernicious anæmia was first described by Dr. Walter Channing, of Boston (*New England Quarterly Journal of Medicine*, 1842), for in an article entitled "Anhæmia, particularly in Connection with the Puerperal State and with Functional Disease of the Uterus, with Cases," he evidently portrayed certain types of the disease, though he had not the modern means at his command for effecting a diagnosis. And there is also reason to believe that quite a number of Boston physicians were more or less acquainted with pernicious anæmia as early as 1830. Twenty-five years later Addison described it under the name of *idiopathic anæmia*, though it is claimed by transatlantic writers that he had spoken of its essential features when lecturing to students in 1842. The most important contributions to our knowledge of the subject, however, have been made since the time of Addison, notably by Wilks ("Wilks and Moxon's Pathological Anatomy," p. 636), the veteran pathologist, and others who have been in and about Guy's Hospital, who first appears to have pointed out that in this form of anæmia there is a marked fatty degeneration of certain organs, especially of the heart. In the years 1871–72, Biermer, of Zurich, came forward with new views on the subject, fancying, however, that he had discovered a disease hitherto unknown.

He first directed our attention to the marked changes in the blood, and their importance in making a differential diagnosis. During the past sixteen years contributions have been numerous and important, and American physicians have added their full share to the accumulating fund of information.

---

[2] Read before the Clinical Society of the New York Post Graduate Medical School and Hospital, February 18, 1888.

The names that are usually employed to designate the disease are as follows: idiopathic anæmia, essential anæmia, and progressive pernicious anæmia. Personally, I dislike the first of them, because the term idiopathic suggests that there is *no* cause, whereas there is a real cause for it, as for every disease, though we have certainly failed to discover it in this particular instance. The word *essential* in medical terminology indicates, as applied to a particular disease, that it is not dependent on another disease. Now, this may or may not be true of this variety of anæmia. The word pernicious correctly describes the gravity of the affection, and the word progressive a very uniform characteristic. Using the two together, we depict a form of anæmia that cannot be well mistaken, and it will certainly serve us until we have a clearer knowledge of the etiology of this and of some other forms of blood disease.

It may be proper to say at this point that, while we find the term anæmia convenient, it does not aptly describe the true condition of the individual. It is not so much that there is a lack of blood—if, indeed, there be any lack—but a deficiency in some of the normal constituents of the blood, as we shall see at another place.

Let us now note some of the clinical characters of progressive pernicious anæmia. It appears to be doubtful whether one sex is more prone to it than the other. For, though Fagge ("Pract. of Med.," vol. ii., p. 609), in twenty-eight cases that occurred at Guy's Hospital, found that sixteen were males and twelve females, others, whose experience has been in the line of obstetrics, have found it more frequently in women than in men. On the other hand, in studying a greater number of cases, it does not appear that sex has any positively determining influence. Pernicious anæmia is most common in the middle period of life, between twenty and sixty years of age, and is rarely found under fifteen or over sixty years of age. It does not appear to have ever occurred under the age of five years.

As the disease has not been so carefully studied in some localities as in others, we have been led to infer by statisticians that it is comparatively infrequent in certain countries. And so it happens that, while instances of the disease have often been reported in England, France, Germany, and Switzerland, some countries, like our own, have been thought to be exempt. While, however, I believe that the disease is by no means common in New York, it does really occur here, and there have been instances in most, if not all, of our general hospitals. And a recent writer (Musser: Wood's "Reference Handbook," article "Idiopathic Anæmia"[1]) instances no less than forty-two cases occurring in the cities of Philadelphia, Montreal, and Toronto. Reasons for failure to detect the disease will be given further on.

There seems to be an effort on the part of some pathologists to separate this malady into the primary progressive pernicious and the secondary. Such persons would find that in a certain number—the majority—no derangement of the health has preceded the attack, while, in what they would call sequential anæmia, there have been a number of ailments or, at least, unusual states of the system. In the present state of our knowledge, it seems hardly worth while to make these divisions, because we have yet to learn that the antecedent conditions, which have been described here, had any causal relation with the disease. Some of them may be enumerated, however. They are: (1) The parturient state, especially when there has been hemorrhage, or prolonged lactation; (2) inadequate food; (3) yellow fever; (4) mental shock or anxiety, and lastly, (5) infection by parasitic disease. And I would venture to suggest that in this last named direction we may well look with more care in endeavoring to find a causative factor. Now, though hemorrhages and mental disturbances have been quite frequently assigned as causes, we should not fail to remember that, as a rule, the disease develops without assigned cause; and this characteristic was urged by Addison in his description, which I will now quote, because it is a most remarkable pen-picture of the disease. He says: "It (pernicious anæmia) makes its approach in so slow and insidious a manner that the patient can hardly fix a date to the earliest feeling of that languor which is shortly to become so extreme. The countenance gets pale, the whites of the eyes become pearly, the general frame flabby rather than wasted, the pulse perhaps large, but remarkably soft and compressible, and occasionally with a slight jerk, especially under the slightest excitement. There is an increasing indisposition to exertion, with an uncomfortable feeling of faintness or breathlessness in attempting it; the heart is readily made to palpitate; the whole surface of the body presents a blanched, smooth, and waxy appearance; the lips, gums, and tongue seem bloodless; the flabbiness of the solids increases; the appetite fails; extreme languor and faintness supervene; breathlessness and palpitations are produced by the most trifling exertion or emotion; some slight œdema is probably perceived about the ankles; the debility becomes extreme; the patient can no longer rise from his bed; the mind occasionally wanders; he falls into a prostrate and half torpid state, and at length expires; nevertheless, to the very last, and after a sickness of several months' duration, the bulkiness of the general frame and the amount of obesity often present a most striking contrast to the failure and exhaustion observed in every other respect."

With such a description one could rarely fail to make a diagnosis. We have but little to add to the clinical picture. It may, however, be said that vomiting is a very distinguishing symptom; that fever of an irregular intermittent type is usually present, that hemorrhages are frequent, and that a microscopic inspection of the blood will reveal changes that are unknown to any other disease; though on this point I may differ from a very able observer and may be wrong (Fagge, *loc. cit.*, p. 610).

The changes in the blood are as follows: Besides the deficiency in the red globules there are corpuscles present which are not usually found in normal blood. They are very small, globular, and of a deep red color. Whether the presence of micocytes is pathognomonic may be uncertain, but they occur in almost all, if not all, cases. Besides these are nucleated red corpuscles, which are also found in the adipose tissue of the body.

There is little in the macroscopic morbid anatomy of this disease that throws light on its character. Fenwick once found atrophy of the hepatic lobules, and conjectured that this condition might have caused the dyspepsia and vomiting. Pepper, in 1875, first observed that the fatty tissue of the long bones was replaced by the red marrow of infant life. The color is at first purplish, and then light red. Changes in the nervous system have also been noted, but they are said to occur in other forms of anæmia.

There is usually no insuperable difficulty in making a diagnosis, but it should be done by exclusion, mainly. It is not possible to make a diagnosis until the case has been under observation some little time; we have to differentiate from chlorosis, anæmia from losing blood, from known parasitic causes, from malignant disease, Bright's disease, Hodgkin's disease, from malarial and syphilitic disease, and phthisis. In the absence of any one of these, and with the pallor, dyspeptic symptoms, apathy, and changed conditions of the blood, there need be no error committed, though, as a matter of fact, mistakes are sometimes made even among our best clinicians. It is almost uniformly a fatal disease, though treatment may possibly hold the disease in check for some years, if early applied. Death usually takes place in from three months to one year, but patients have lived for upwards of seven years. In so far as treatment is concerned, iron is useless, and though phosphorus has been vaunted, there is probably but one remedy that is of utility. It is arsenic. Possibly this mineral sometimes effects cures, and this opinion is held by Pye-Smith, of London. Personally, I have never known a case to be cured, but the reason of my pessimistic view of treatment may be due to the fact that the disease was not seen in its early stages. It is very desirable that we should collect, as speedily as possible, all data bearing on this point, and the two cases which I append may, therefore, be useful in adding a trifle to existing data.

---

[1] The reader who is interested in the subject of pernicious anæmia, will do well to consult this article, which contains a good list of bibliographical references.

Case I.—M——, a middle-aged man, was admitted to the Post-graduate Hospital, under my care, as a private patient, on December 3, 1887, and gave the following history: He had led an active life, as a laboring man, in a position where his health was not in any way jeopardized, nor had he been obliged to work for his living, as his family was in comparatively easy circumstances. A few months before admission he was taken with diarrhœa and vomiting. His physician had treated him presumably for malarial anæmia, and he had taken quinine in large quantities, but without avail. The diarrhœa had exhausted him extremely. Thanks to the devotion of his children, he had never wanted for anything that money could provide. When he appeared at my clinic, on December 3, 1887, he was extremely weak, had a soft, compressible, and rapid pulse, with rapid respiration. The pallor of his countenance and the whiteness of his mucous membranes was extreme; but he complained of no pain or distress of any kind. On examining his chest I found indications of slight œdema of the lungs, at their bases, and some hydropericardium. He was exhibited before the class as a case of pericardial effusion. The sac was dilated and the heart-sounds were muffled. The impulse was also faint. Area of præcordial dulness enlarged. Slight œdema of face and of extremities. When admitted to his room the temperature was 99.8°; pulse, 87; respiration, 24. Suffering from great irregularity of the pulse, he was put upon the infusion of digitalis. A blister was also applied for the hydropericardium. The patient slept well, and in the morning his pulse had fallen to 84; the respiration to 18. Vomiting was arrested by beef-tea and oat-meal gruel at short intervals. Patient expressed himself as feeling very comfortable. On December 7th he had several very loose movements, and felt much exhausted, so that stimulants were ordered him. On December 8th he vomited for the first time after admission, but it was perhaps due to opiates taken to check his diarrhœa. Temperature, 98.5° to 99.4°; pulse, 84 to 90; respiration, 22 to 24. Sulphate of quinine and iron, in moderate doses. Whiskey, one-half ounce every two hours. December 11th: Examination of blood. Red globules, 1,425,000. The red corpuscles are much deformed, some swollen and colorless, and some nucleated. December 13th: Temperature, 98.4°; pulse, 94; respiration, 21. The amount of urine slightly diminishing, but is not abnormal otherwise. December 20th: Temperature, 101.4°; pulse, 102; respiration, 22. December 21st: Temperature, 101.4°; pulse, 116; respiration, 22. December 22d: Patient attempted to sit up, but was too weak. Was now put on Fowler's solution, in three-drop doses. To-day he coughed up some blood. December 23d: Vomiting has again begun. December 24th: Patient is with difficulty aroused. Temperature, 100.5°; pulse, 114; respiration, 24. On December 27th, transfusion of a saline solution was resorted to, and repeated on December 28th. Patient died December 28, 1887, at 9.40 p.m. No post-mortem examination obtained. The patient was apathetic during the whole course of his sickness.

Case II.—M. A. C——, aged twenty-seven, England, was admitted to St. Luke's Hospital during my service there as pathologist, on October 1, 1879. Father and mother probably died of consumption. Patient had enjoyed excellent health until a few months ago, when she had an attack of intermittent fever. Œdema of the feet followed. Quinine stopped the malaria, but her hair fell out. Three weeks before admission she was exposed to severe weather and had a thorough wetting. On the following day she vomited a great deal, and continued to vomit ever since. She also became very anæmic. No appetite. She was a woman of dark complexion, somewhat jaundiced, but the body was well covered with fat. Slight œdema of feet and legs. No fever. Tongue large, pale, and flabby. Slight attacks of pain extending from epigastrium to back and into lumbar regions. Frequent nausea and vomiting of food and clear yellow fluid. Lungs, kidneys, and heart normal. Urine abundant. Sleeps well.

Under treatment by the citrate of iron and quinine the patient improved, the vomiting was lessened, and œdema diminished. Seventeen days after admission the patient suddenly became restless, the breathing stertorous, the pulse became greater, and the patient died of heart-failure.

At the post-mortem examination it was found that the apparent plumpness was largely due to subcutaneous œdema. On opening the thoracic cavity the heart-sac was found to contain thirty-eight ounces of a clear, serous fluid. The lungs were found normal, except that there was a small cheesy nodule at the apex of the right lung, and that this organ was encased by a fibrous deposit. The spleen was enlarged and flabby; weight, sixteen ounces.

The kidneys were pale and white. In the pelvis numerous ecchymotic spots were seen. The liver was considerably enlarged. Weighed sixty-six ounces. The gall-bladder contained two gall-stones. Both kidneys and liver were found infiltrated with small, round corpuscles. All the bones of the body were soft, the ribs especially. This case was diagnosticated as one of pernicious anæmia, and the condition of the bones and of the adipose tissue, with the dropsical and dyspeptic symptoms, would sustain this view. I can find no notes bearing on the examination of the blood, so that an important diagnostic criterion is absent from the case. And I would take occasion to say, in conclusion, that in cases of this sort, and, in fact, in all grave cases of anæmia, the physician will find great advantage in using some instrument for determining the number of the red and of the white blood corpuscles. In pernicious anæmia, especially, any good hæmatometer will furnish us with the most important data for forming a differential diagnosis. And in my opinion the physician who makes use of this instrument in suspected cases will *never* fail to make a diagnosis, if he finds the peculiar condition of the blood referred to, in the absence of the diseases I have already enumerated.

In blood-counting I have latterly employed Gowers' Hæmatocytometer, a better instrument than any I have heretofore used.

17 East Forty-fourth Street.

Some Dermatological Negatives.—Psoriasis is never seen upon the tongue. Ringworm of the scalp is not found in grown persons. Lupus (vulgaris) is a specific disease, and is not due to syphilis. Arsenic does not cure, nor even improve, *all* skin diseases. Eczema is not pronounced ec-*ze*-ma. Premature baldness is not always hereditary, but, on the contrary, is frequently due to neglected dandruff. Lotions are not, as a rule, as good for applications as ointments. The majority of cases of eczema display no vesicles; and the vesicles, when present, are frequently small and quickly broken. The animal parasitic diseases cannot always be diagnosticated by observing the presence of the parasite. Papular syphilis is not "syphilitic psoriasis." Skin diseases frequently penetrate deeper than the skin, and the study of them is deeper still. Acne is not cured in a day, nor pemphigus in a week. The skin presents sixteen square feet of exposed surface, and is unlike other organs, inasmuch as it is more liable to frequent irritation from without. Non-volatile substances dissolved or suspended in water are not absorbed by the skin to any appreciable extent.—*Philadelphia Medical Times.*

REPTILIAN HEART;

OR, RUDIMENTARY AURICULAR SEPTUM, RUDIMENTARY VENTRICULAR SEPTUM, OBLITERATED PULMONARY ORIFICE AND TRUNK, ABSENCE OF PULMONARY VEINS, ABSENCE OF MITRAL ORIFICE, ANOMALOUS VEINS AND ARTERIES.[1]

By W. P. NORTHRUP, M.D.,

NEW YORK.

THE child from which this specimen was taken lived thirty-one days; its chief symptom was cyanosis (a "blue-baby"). At death it was found to have one auricle and one ventricle.

A female child, two weeks old, was brought to the New York Foundling Asylum and entered upon the books with the note, "Condition miserable—cyanosis." She remained under observation two weeks, continuing in the same miserable condition, becoming temporarily less and more cyanotic, and died at the age of one month.

Diagnosis during life was patent foramen ovale and ductus arteriosus.

Autopsy.—The body was small, weighing seven and a half pounds, poorly nourished, and livid, more especially about the head and upper portion of the trunk. The heart inclined to the right side at the angle it usually bears to the left, the left lung, however, bearing the usual two lobes. Posterior portions of both lungs were congested; otherwise normal. The pleura, pericardium, and peritoneum contained a small quantity of clear, straw-colored fluid. The heart consisted of one auricle, into which emptied two veins, the superior and inferior vena cavæ, and one ventricle giving off one artery, the aorta. The ventricular walls were of uniform thickness, showing, without, an intraventricular groove, and within, a ridge of rudimentary septum. The auricle presented externally the usual outline of two auricles with their appendices. Within there was a thin triangular membrane, having the location and appearance of an enlarged Eustachian valve; otherwise, there was no attempt at partition. The superior vena cava opened by a valve-like orifice to the left of the rudimentary septum, corresponding nearly to the usual position of the pulmonary veins. The inferior vena cava opened in its normal position at the right of the base of the Eustachian membrane.

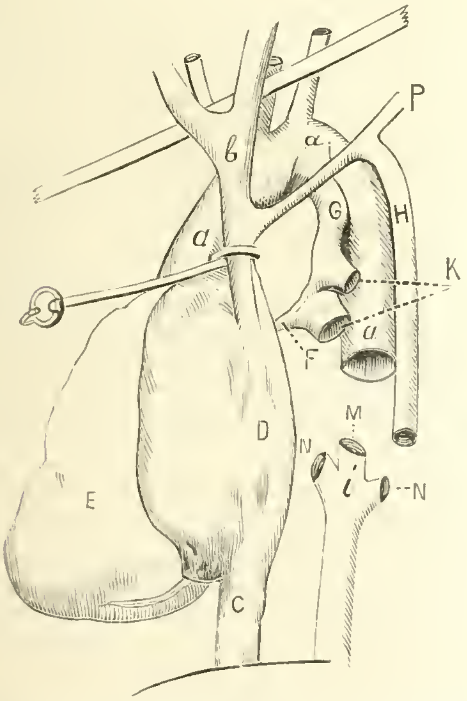

FIG. 1 (life size).—Shows the heart in position. *a*, Aorta; *b*, vena cava superior; *c*, vena cava inferior; *d* and *e*, auricle and ventricle; *f*, rudimentary pulmonary artery; *g*, ductus arteriosus, patent; vena azygo, anomalous; *i*, gastro-hepatic artery, anomalous; *k*, pulmonary branches from ductus arteriosus; *n*, pulmonary veins; *p*, superior intercostal vein.

The pulmonary artery was represented by a fibrous string attached to the base of the heart in the angle formed by the right auricle and origin of the aorta. Its orifice had no rudimentary trace, and its trunk, as far as the ductus arteriosus, was impervious.

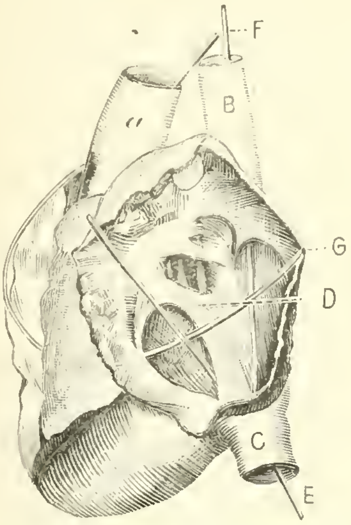

FIG. 2 (life size).—Showing anterior half of auricle laid open. *a*, Aorta; *b*, vena cava superior, through which passes a probe into left half of auricle; *c*, vena cava inferior, through which passes probe (*e*) into right half of auricle; *d*, rudimentary septum or persistent Eustachian valve; *g*, probe passing through auriculo-ventricular opening and out through aortic orifice.

The aorta was given off from the common ventricle in the median line, having upon its right the interventricular groove and rudimentary pulmonary artery. Its relation to the left heart was obvious.

The superior vena cava passed down the median line to the left of the aorta, instead of taking its usual course upon its right.

The valves of the heart were two in number, the usual valves of the aortic orifice and the tricuspid auriculo-ventricular.

Ductus arteriosus Botalli was pervious and equal in calibre to the innominate artery. It descended from beneath the arch of the aorta in a wavy, twisted course for half an inch, when it was joined by the fibrous rudiment of the pulmonary trunk, at this point giving off several branches to each lung.

Below the root of the left lung was a large vessel, receiving blood from the ductus arteriosus by a small straight trunk (Fig. 1, *m*, represented here too large), and from a large vessel coming from each lung. This vessel was without valves, one-third the size of the aorta, conducting arterial blood, and receiving most of its current from the pulmonary veins. It seemed to be physiologically the pulmonary veins, but, instead of emptying into an auricle, it continued downward in an anomalous course, and applied itself to the lesser curvature of the stomach, giving to that organ a rich supply of branches and continuing out to furnish a large trunk to the liver. It was then pulmonary vein and gastro-hepatic artery.

At the usual position of the cœliac axis the aorta gave off a group of arteries as follows: Two renal, superior mesenteric, and splenic.

There were also anomalies among the veins. The left common iliac emptied into the left renal vein. The right common iliac received the blood from the right renal and joined with the left renal at the border of the liver to form with the hepatic vein the inferior vena cava. The azygos veins, major and minor, were represented by an anomalous vessel of large size running along the left side of the aorta, which, having received the superior intercostal, curved forward over the arch of the aorta and emptied into the superior vena cava.

---

[1] Presented at a meeting of the New York Pathological Society.

The circulation, then, was maintained by single heart. The auricle received the customary vessels of the right side; the ventricle discharged its blood into the aorta. At each circuit a portion of the current was turned aside to pass through the lungs, become aërated, pass on to the viscera, return by a short route to the auricle and ventricle, and thence for the most part to pass to the general circulation.

From likeness to the blood-course in lower forms of life, this heart is denominated "reptilian."

THE DIAGNOSIS OF EAR DISEASES WITHOUT INSTRUMENTS.[1]

By HUNTINGTON RICHARDS, M.D.,

AURAL SURGEON AT THE NEW YORK EYE AND EAR INFIRMARY, AND CHIEF OF CLINIC IN EAR DEPARTMENT OF THE VANDERBILT CLINIC, NEW YORK.

The title which I have chosen for the following brief paper is one which will surely be accounted a contradiction in terms, both by an otological specialist, and by a general practitioner who has had any considerable experience in diseases of the ear. The subject-matter of the paper is, nevertheless, one which should interest medical men, whether they be "specialists" or "family physicians;" and if it fail to do so in this instance, or if the paper prove quite barren in suggestions of a practical kind, it will be the fault of the writer alone.

Accurate diagnosis, in the case of a vast majority of diseases of the ear, is certainly impossible without the aid afforded by properly-constructed instruments, and is not invariably easy of accomplishment, even with this aid. On the other hand, it will not be disputed that in many cases of aural disease relief is first sought, and must be first sought, at the hands of a physician, who either has no good apparatus for examining the ear, or who lacks experience in the handling of such apparatus. Moreover, in many cases of aural disease, right diagnosis in the very earliest stage of the disease is a matter of the greatest importance. Particularly is this true of that class of cases wherein a disturbance in the function of hearing is the leading symptom; for, unless the family physician be on the watch for the first beginning of the disease and knows how to recognize its symptoms, an incurable deafness is but too often the result.

It is well known that chronic suppurative disease of the middle ear very frequently begins in childhood, or in early infancy; sometimes as an acute inflammation of the tympanum occurring during the course of, or as a sequela to, an attack of scarlet fever, measles, diphtheria, or whooping-cough; sometimes as an accompaniment of, or sequela to, the far milder "cold in the head" or a common sore throat. It is not so well known, or, at least, it is too apt to be forgotten, that the disease in question, instead of commencing as an acute attack, is sometimes very insidious in its beginnings; that often it is, to all appearances, quite independent in origin of other pathological conditions; and that, when violent in its onset and occurring in an infant or young child, its symptoms may be readily misinterpreted as indications of disease of the brain.

The damage to the hearing caused by this disease, and the many annoyances to which it subjects the patient and the patient's friends, are also widely, but not fully, appreciated. The dangers of the disease are by no means properly appreciated; although the saying of Wilde, "So long as otorrhœa" (meaning otorrhœa of tympanic origin) "is present, we never can tell how, when, or where it will end, or what it may lead to,"[2] is as true now as it was the day it was uttered, twenty-five years ago.

The importance of early diagnosis in the case of suppurative disease of the tympanum cannot be over-estimated; the same is true of the non-suppurative forms of disease in this cavity, both acute and chronic, and it is self-evident that upon the family physician must fall the responsibility of making such diagnosis. The preventive treatment of these and of all other affections of the ear is wholly in his hands; the curative treatment is largely in his hands, at times it is wholly so; and it is the manifest duty of every physician to make himself more familiar with the etiology of aural diseases than he is apt to be at the time of graduation, to perfect himself so far as he can in the methods of diagnosis applicable to such cases, and, when not in possession of the instruments of diagnosis, or when unskilled in their use, at least to familiarize himself with such non-instrumental methods as may lead him to the formation of an approximately correct opinion concerning the nature of the affection with which he has to deal.

Diseases of the auricle require for their diagnosis no special apparatus. On the other hand, diseases of the external auditory canal, and those of the middle and internal ear, do require such apparatus for their accurate diagnosis, although a probable, or an approximate, diagnosis of them can sometimes be made without any apparatus whatever. The history of the case, as to the presence or absence of such symptoms as deafness, pain in or about the ear, a discharge from the auditory canal, itching of the skin lining the latter, etc., will often give valuable information upon which to form a probable diagnosis, especially if due attention be paid to the comparative severity of each symptom, to the manner, time, and frequency of its occurrence; and, when two or more such symptoms are present in a given case, to their relative sequence, or the order in which they have appeared, and to their relative severity and relative frequency. The character of a discharge, where such is present, will often be an aid to more accurate diagnosis. Thus, for example, a mucous discharge, or a purulent or serous discharge, containing an admixture of mucus, points infallibly to disease of the middle ear, with loss of continuity in the tympanic membrane. The occasional appearance of blood in a chronic discharge is a pretty sure indication of the presence of polypoidal growths in the ear, or of granulations which may lead to such growths. A malodorous discharge frequently, but by no means always, points to the tympanum as its place of origin. The purulent or sero-purulent discharge of a chronic external otitis is apt to have a bad odor, peculiar to itself, and by this peculiarity is easily differentiated from the equally, or even more, badly smelling discharge of tympanic disease. A discharge from the ear, accompanied by persistent itching of the canal, is usually due solely to otitis externa of the eczematous variety, although the mere presence of itching by no means excludes tympanic disease.

Pain in the ear, increased by traction on the auricle, is a symptom rather of external, than of tympanic, otitis; although such traction may increase the pain in either case. Noticeable displacement of the auricle is, as a rule, found only in cases of severe otitis media. Pain in the ear or head, combined with swelling, tenderness, and redness of the integument behind the auricle, are frequently, but not always, indicative of severe inflammation located in the tympanic cavity and involving the antrum and other mastoid cells; while, as a general rule, where the swelling and tenderness are located below, rather than behind, the auricle, they point to the extra- rather than to the intra-tympanic portion of the ear as the seat of the trouble which has given rise to them.

Deafness unaccompanied by discharge or by pronounced pain, is usually a symptom of middle-ear catarrh of the chronic or of the mild subacute variety; following upon persistent itching of the auditory canal, it may indicate obstruction of this channel by exfoliated epithelium, or by an inflammatory thickening of its walls; when very sudden in its onset, and especially when it has been first observed directly after bathing the head or washing the ears, such deafness may be due to the presence of water at the fundus of the canal, or to impaction of cerumen—quite as frequently to the latter as to the former. Sudden and pronounced deafness occurring in a patient who has a syphilitic taint, is very apt to arise from specific involvement of the internal ear; including in this term the auditory nerve throughout its course, from the points of origin in the cerebellum and medulla oblongata to its terminal distribution in the cochlea, vestibule, and ampullæ of the semicircular canals. When we are told that a patient's deafness has been of long duration, that it has not been accompanied by any discharge from the ear at any time (a point, by the way, concerning which the history given by the patient, or by his friends, is often misleading), and that it varies considerably with seasonal or weather changes, it is probable that we have to deal with that commonest of all aural affections, simple chronic catarrh of the tympanum. The diagnosis, under such circumstances, is rendered more probable by a discovery of the symptoms and visible signs of chronic nasal and naso-pharyngeal catarrh, or by a history of past trouble from this affection. This chronic middle-ear catarrh is the disease which is responsible, in greater degree than all other aural affections combined, for the "hardness of hearing" of adult life, and for the deafness, in its slighter degrees, often mistaken for "inattention," of school children. Nay, more than this: to it, and to it alone, are unquestionably to be attributed a goodly percentage of cases of deaf-mutism, and by its early detection and treatment this great affliction could often be averted.

---

[2] Practical Observations on Aural Surgery. Philadelphia: Blanchard & Lea. 1853.

The history of an injury inflicted by a blow, or incurred by a fall, together with the sudden onset of a deafness which is accompanied by noises in the ear and by dizziness or faintness, may point merely to a sudden impaction of cerumen or of a foreign body in the auditory canal, or may indicate a traumatic rupture of the membrana tympani. Followed immediately, or within a few days, by an odorless discharge of blood-stained serum, more or less profuse in amount, such a collection of symptoms and a history of such an injury would point with tolerable certainty to traumatic rupture of the membrane; and a noise in the ear made by inflation, according to Valsalva's method, when loud enough to be heard by the examiner, would confirm the diagnosis to the point of almost absolute certainty; provided, always, that the patient be seen very shortly after the occurrence of the supposed or alleged injury, and that it be possible to exclude the pre-existence of disease of the middle ear.

Concerning the symptoms of tinnitus aurium, vertigo, reflex ear cough, vomiting from mechanical irritations of the ear, from disease of the internal auditory apparatus, or as a symptom accompanying middle-ear disease, and concerning convulsions due to aural disease, I shall not attempt to speak; one symptom, of rather unusual occurrence, viz., the so-called "autophony," an exaggerated hearing by the patient of the tones of his own voice. is worthy of passing mention as being highly characteristic of obstruction in the external auditory canal, and also an accompaniment of middle-ear catarrh. The congeries of symptoms generally considered characteristic of the so called "Ménière's disease," I shall merely allude to in order to remark that this pathological condition is about the rarest and least understood of all diseases affecting the ear, and that its symptoms are not pathognomonic.

When speaking of traumatic ruptures of the drum-membrane, I made mention of Valsalva's inflation. Where the Eustachian tube remains fairly pervious, this simple and well-known procedure may often be of service in confirming the diagnosis of any perforation of the membrane, whether traumatic or pathological in origin. But the physician will do well to avoid its use where pain in the ear is present, and also in cases of long-standing deafness where he is unable to get a view of the drum-membrane. A fair view, sometimes a very good view, of this membrane may, under certain circumstances, be had without the employment of a speculum or forehead-mirror. This will be the case where the patient has an auditory canal of exceptionally large calibre, and one which is exceptionally straight in its general direction or axis, and is free from the usual tortuosities. Gentle traction of the auricle, in a direction upward, backward, and outward in the case of an adult; downward, outward, and backward in the case of a child, will materially aid in straightening the canal. For illumination of the canal reflected light may be thrown into it from a common hand-mirror, and in this way a substitute may be found for the vastly superior concave forehead-mirror, concerning the use of which, as well as of the aural speculum and all other instruments of diagnosis, I have by the title of this paper pledged myself not to speak.

For the same reason, as well as from lack of time, I am practically debarred from any allusion to some of the rarer forms of aural disease, and from a discussion of the diagnostic import of the various stenoses of the auditory canal, and of the polypoidal growths which are too often, and other pathological growths which are but rarely, found therein. These stenoses and growths may sometimes, indeed, be detected without the use of any form of instrument; but their full extent, exact form, and precise location can very rarely be appreciated, or their diagnostic value duly estimated, without the use of the speculum and forehead-mirror, and it may be of the probe and other instruments as well. With rare exceptions, also, foreign bodies in the ear call for the use of the speculum, at least to insure a proper degree of knowledge respecting their nature and position; and their mere presence in the ear can often be ascertained only by one made familiar by practice with the use of this almost indispensable instrument.

I trust that those to whom I have presumed to address these remarks will be able to believe me, when I tell them that I purposed laying before them in this paper, not rules indeed, but hints, by which they might be in some measure aided toward a correct diagnosis of the commoner affections of the ear. In practice I myself constantly find such points as have been herein touched upon an aid to diagnosis; although, being in the habit of employing instruments for diagnostic purposes, I never realized how very dependent I was upon the use of tools until I had attempted to tell others how much could be done without them. I do not doubt you will believe me when I add, that a close adherence to the limits marked out by its title has balked my pen at every sentence, I may almost say at every word, of this paper; and while I feel that I must apologize for having given those whom I have addressed a very meagre stock of information concerning the diagnosis of ear diseases, and that my remarks, regarded under the aspect of instruction in such diagnosis, are a fairly apt illustration of the "lucus a non lucendo;" nevertheless, I trust that I have negatively succeeded, in that I have presented a tolerably clear demonstration of the fact that, without instruments there is no *accurate* diagnosis of ear diseases, even though in exceptional cases an *approximate* diagnosis may be possible to one who is deprived of their aid; while in all cases valuable guidance toward a really accurate diagnosis is furnished, by the symptoms and history of the disease, to one who supplements these by the much greater assistance afforded by an instrumental examination of his patient.

EXPULSION OF THE PLACENTA.—Dr. S. W. Squires, of East Avon, N. Y., writes: "When the after-pains are tardy and the obstetrician wishes to hasten their appearance, it can be quickly effected by instructing the patient to take a deep inspiration and blow against the back of her hand. I have never known it to fail to bring on uterine contraction immediately. Of course blowing on the hand has nothing to do with the phenomena; it is the full inspiration that stimulates the uterine contractions. This is a practice I always follow with the most gratifying result of getting the woman soon bandaged up after the birth of the child."

A NEW METHOD FOR SUPPLYING THE CONTINUOUS OR GALVANIC CURRENT IN THE TREATMENT OF FIBROID TUMORS OF THE UTERUS.

By A. B. CARPENTER, M.D.,

CLEVELAND, O.

EVERY physician who has had occasion to use electricity knows well the difficulty he has experienced in keeping his battery in working order.

Change in temperature, the dry and moist condition of the atmosphere, evaporation, polarization, the frequent inspection, renewal of the battery elements and fluids, together with the labor and expense incurred, has placed a tax upon the time of the busy practitioner, and made the operating of large batteries no trivial matter and withal a burden.

The treatment of fibroid tumors of the uterus, according to the Apostoli plan or method, necessitating, as it does, a large number of cells, has only resulted in increasing this burden, and, I venture to predict, that after the renewal, once or twice a year, of the battery elements, to say nothing of the labor in keeping the fluids in proper condition, will necessitate not a few physicians to discard this valuable form of treatment, and result in expensive plants falling into comparative disuse.

So long as electrolytic work was confined to the use of a small number of cells, the labor and expense of keeping in order was proportionately light; but with our increasing knowledge of the subject, together with the more general use of the milliampère-metre, whereby we are more intelligently, as well as accurately informed of the strength of the current used, and thereby giving us the knowledge to administer this form of treatment in great strength on the basis of exact dosage, the task of caring for batteries made up of from seventy-five to one hundred and fifty cells, impose a task that is something formidable.

Dr. F. H. Martin has called the attention of the profession to a small dynamo that he has had constructed with a view to the supplanting of the cumbersome battery, and claims for it both the electrolytic and galvano-caustic currents. It is designed to be run by an electric motor or any other convenient power. I had the pleasure of witnessing a test of the machine while on a visit to Chicago a short time since, and must say that it worked most admirably. I would venture the suggestion, however, that the noise made in running will be somewhat objectionable to it for office use.

The device which we have the pleasure of calling the attention of the profession to consists simply in that of using the current of the incandescent lighting system direct from the street wire passing the door—Thompson-Houston or Edison. We have the wires of the former system placed in our office, and by the means of a rheostat resistance sufficient to reduce the current to a minimum is interposed then by the use of an ordinary switch-board, the current is increased or diminished according as resistance is cut in or out. A milliampère-metre is made use of whereby the current is accurately measured while the patient is in the circuit.

The device is absolutely safe, as the entire voltage of the wire can be handled without the rheostat being used. My wire furnishes a very smooth continuous or galvanic current, with an electromotive force of one hundred and ten volts with a maximum strength of $\frac{1}{10}$ of an ampère, equal to about eighty Leclanché cells. This current is constant, does not vary in voltage, and is always ready, night or day, as the main line from which my connections are made is used for commercial purposes, and furnishes lighting for basements, dark shops, and rooms. This, I am informed, is the case in all large and in many small cities, so that little trouble will be met with in securing a wire with a day current. When a wire is once placed in our office, the task of caring for a battery of cells is at an end, and we have an apparatus that is at once always ready, reliable, economical, cleanly, and durable. The rapid introduction of the incandescent lighting system, together with the great increase in the use of this form of light, will place within the reach of very many physicians this current for electrolytic work.

The charge for the annual rental of the wire is $10, not including the cost of putting in, which, if the main line passes the door, should not exceed $5. This device, as will be seen, does away with cells entirely, as well as the time, trouble, and expense of keeping them in order, and I venture to express as my opinion that we have a current superior to any that it is possible to have generated from chemical action, besides economy of room, which is not a small item in cramped quarters.

A word regarding the danger from contact with the electric-light wire. The Thompson-Houston or the Edison incandescent system of an electromotive force of one hundred and ten volts, and of a strength of $\frac{1}{10}$ of an ampère is harmless, *and must not be confounded with the arc system of Brush and others, as the strength of the latter is six ampères, and of course dangerous and must* NEVER *be used.*

For the purpose of meeting and providing against any unforeseen complications, as well as to anticipate criticism, I have placed at the office terminal of the wire a fuse box, the connections of which are so constructed that they will instantly melt, thus breaking the circuit, should anything unusual occur. Then if it is remembered that the entire voltage amounts to only about eighty Leclanché cells, I think it will be recognized that we have a current at once safe and practical.

I am under obligations to Mr. William D. Graves, of this city, for perfecting and superintending the construction of my apparatus, which, so far as I can now see, fulfils the object for which it was designed, viz., that of supplying the continuous or galvanic current, independent of battery cells.

I may say that I have had the apparatus in daily use since its completion some weeks since, and my expectations have been fully realized by the simplicity and beauty of its action. The apparatus is not patented, and I shall endeavor to place the models in the hands of some reputable electric manufacturing company to insure the profession against extortion.

143 EUCLID AVENUE.

IODINE TRICHLORIDE.—Iodine trichloride has been brought forward as a disinfectant and germicide. It is prepared most conveniently by passing a full current of chlorine into a three-necked flask, into which iodine is vaporized from a small retort fitted to the central neck. The trichloride forms orange-yellow crystals, which are darker if contaminated with the liquid monochloride. This compound is rather freely soluble in water, forming a strongly acid, yellow liquid, with a somewhat penetrating, pungent odor. Although soluble also in ether and alcohol, the alcoholic solution undergoes change, even in the cold, chloral being formed. Strong aqueous solutions keep better than dilute preparations, the latter undergoing decomposition, especially when subjected to direct light, hydrochloric and iodic acids being formed, as well as monochloride of iodine. Professor von Langenbuch reports that its germicidal action far exceeds that of carbolic acid, and comes nearer to that of corrosive sublimate, over which it possesses the advantage of being relatively non-poisonous. He considers an aqueous solution of the trichloride of iodine of the strength of 1 in 1,000, or 1 in 1,500, as equal to a four per cent. carbolic acid solution, or a 1 in 1,000 or 2,000 sublimate solution, for the disinfection of wounds, the hands, or instruments. A solution ot 1 in 1,200 is recommended as an injection for gonorrhœa, or taken internally, in the dose of a teaspoonful every two hours, as a remedy for dyspepsia dependent on the presence of bacteria in the stomach or intestines.—*The Provincial Medical Journal,* February, 1888.

Progress of Medical Science.

A Rapid and Simple Method of Reducing Dislocation of the Shoulder.—In all the methods ordinarily employed for the reduction of dislocations downward of the humerus the trunk is fixed and the head of the humerus is raised into the glenoid cavity. Dr. Abril inverts this proceeding; his plan is to fix the humerus and to make the glenoid cavity descend on to the head of the humerus. He claims for his method that it is most simple, easily and quickly done, that chloroform is not necessary to obtain muscular relaxation, that the pain is trifling, and that no assistants are required. He makes the patient stand with a crutch in his axilla; he then holds the hand of the affected side, making slight traction downward; the patient is now to let himself down as if he were going to fall on his knees, and as he falls the head of the humerus glides into its normal position, and the patient is surprised at finding himself cured.—*The London Medical Record.*

The Physiological and Therapeutical Action of Hypnone.—The medium dose in adults is from five to six grains. When given in quantities greater than eight or ten grains it causes pain and heat in the stomach. Dr. Pensato administers it in capsules, two and a half grains. He finds that as a hypnotic it is not inferior to chloral, and it does not depress the heart's action. In phthisis it answers well, in doses of three capsules at bedtime. The patient generally has a quiet night, with some hours' sleep, the cough is lessened, and the patient wakes refreshed, without pain or headache. Hypnone has a decided antifermentative and antiseptic action. It delays the ammoniacal decomposition of the urine, and prevents the alcoholic fermentation of sugar and yeast; it delays, too, considerably the putrefaction both of organic animal and vegetable substances. Thinking that this antiseptic action might be useful in phthisis, and having found that when given as a hypnotic the cough and expectoration was notably diminished, Pensato has lately given it as an inhalation, five drops every four hours. The effect is undoubtedly good—the cough is lessened, and the expectoration altered both in quantity and quality; in one case the purulent sputum became mucous. In some cases, but not in all, the temperature was lowered. Dr. Pensato thinks that these results are sufficiently encouraging to warrant a further trial of these inhalations.—*La Medicina Contemporanea.*

Mesenteric Cyst.—At a recent meeting of the Bradford Medico-Chirurgical Society, Dr. Horrocks reported an instance of this rare disease. The patient was a married woman, aged thirty-one. Before admission to the hospital the tumor had been aspirated several times, and a considerable amount of fluid drawn off. In November, 1886, she was admitted with violent pain in the abdomen, vomiting, and diarrhœa. A rounded swelling was found on the left side below the ribs. The motions were frequent, very offensive, and liquid, but never appeared to contain pus. In December she gave birth to an eight-months' child, and after its birth the general outline of the tumor became more distinct. A few days after, she had a severe attack of diarrhœa, during which the lump became smaller and finally disappeared. She shortly afterward left the hospital, but was readmitted on September 1, 1887, for exploration of the swelling, when it was found there was an elastic tumor in the left hypochondriac and epigastric regions, extending under the ribs and nearly as far forward as the umbilicus. It was freely movable under the abdominal walls. The area of dulness over the tumor varied from time to time. There was no vomiting or diarrhœa when liquid food was taken, but she complained almost constantly of pain, and was on this account kept under the influence of morphia. On September 10th an exploratory abdominal incision was made, but the tumor was so firmly fixed to structures around that the wound was closed. On October 1st she became very restless, complained of chills and headache, but no abdominal pain or tenderness. On October 2d the wound had opened up superficially, but the peritoneal borders remained closed. She continued restless, with vomiting and diarrhœa, until she died, on October 7th. After death the superficial layers of the wound were opened, but the peritoneal edges had healed. The general smooth inner surface and thickened regular wall of the cyst would favor the idea that it is a serous cyst of the peritoneum. Such cysts are extremely rare. They are formed by exudation in the interstices of the serous membrane, and hold at first a thick reddish fluid containing blood-corpuscles, cells resembling pus-cells, and colloid granules, besides large quantities of leucin and tyrosin crystals. These crystals may attain a large size, become adherent to abdominal viscera, and empty themselves by fistulous openings.—*The Medical Press*, February 1, 1888.

Cannabis Indica in Tropical and Dyspeptic Diarrhœa.—In an article on the uses of cannabis indica, Dr. J. F. P. McConnell, of the Bengal Medical Service (*The Practitioner*, February, 1888), strongly advocates the employment of this drug in what is termed dyspeptic diarrhœa. He states also that, even in more advanced cases of tropical diarrhœa, cannabis will sometimes prove very useful. All observation and experience in India have led him to believe that this disease is primarily and essentially one of the liver, and that unless means are taken to influence the functional disorder of that organ by cholagogue remedies—*i.e.*, treatment directed to the liver principally—all attempts to control the diarrhœa will prove unsuccessful. And of all such remedies none is so reliable as *mercury*—either in the form of blue pill or gray powder. But while such direct medication is attempted, as for example by the exhibition of a mercurial pill every night or every other night at bedtime, the cannabis may be employed during the day. For this purpose he usually prescribes it in the form of mixture, beginning with ten minims of the *tincture* and gradually increasing the dose to fifteen, twenty, or even thirty minims, three times a day or oftener. A suitable combination is the following:

℞.	Tincturæ cannabis indicæ	♏x.–xx.
	Bismuthi subnitratis	grs. x.
	Mucilaginis acaciæ	ʒ ss.
	Spiritus chloroformi co..........	♏xx.
	Aq. cinamomi *vel* aq. menth. pip..	℥ j.

M.

This mixture may be given before or after food, preferably the latter, and more particularly when the dose of the tincture is increased. By exhibition soon after food the liability to unpleasant symptoms (headache, giddiness, hallucinations, etc.) is greatly reduced, even in persons who are very susceptible to these effects of the drug. In both true tropical diarrhœa and the more simple dyspeptic diarrhœa, cannabis has this distinct advantage—that it in no way interferes with the bile-forming function of the liver, as opium undoubtedly does.

Pneumonia Death-rates.—The death-rate of the British Collective Investigation Committee in 1883 was $19\frac{4}{10}$ per cent. Under the old system, Louis lost (hospital patients) $28\frac{4}{7}$ per cent.; Dietl $19\frac{5}{10}$ per cent.; Grisolle $15\frac{11}{12}$ per cent.; Dasori $22\frac{2}{9}$ per cent.; Laënnec 10 per cent. The last had better results than the British Collective Committee, who consider the $11\frac{3}{5}$ per cent. death-rate among total abstainers a favorable one. The modern death-rate among the same class as were treated by Louis, is about as high, if not higher (26.6 per cent.) since the intemperate were excluded from enumeration (death-rate 40.5). Grisolle found his death-rate under thirty years of age to be $7\frac{1}{7}$ per cent.; the British death-rate was $8\frac{16}{23}$ per cent. Bennett found the death-rate in the army and navy to be $7\frac{9}{13}$ per cent.; the modern death-rate was $14\frac{2}{7}$ per cent.—*Medical Standard.*

THE MEDICAL RECORD:

SULPHUROUS ACID IN THE TREATMENT OF PULMONARY CONSUMPTION.

THE French seem determined to get sulphur in some form into the body to cure pulmonary consumption. Dr. Darien (*Bulletin Général de Thérapeutique*, t. cxi., 14) gives the history of the treatment with sulphurous acid. It had been used as far back as the second century. Dr. Solland came upon this treatment accidentally in the following way: It seems that a sergeant having phthisis had been through different kinds of treatment, and was finally sent to the East without improvement. Nothing could stay the march of the malady, and weary of continued hospital treatment, he demanded his release and left. Wishing some light employment, he was given the work of opening the doors of the rooms of the barracks where sulphur was burned for disinfecting purposes. To do this he was obliged to pass nine hours of his time each day in a sulphurous atmosphere. In sixty-five days he had completely recovered. A case of chronic bronchitis also recovered after inhaling for fifteen days. M. Auriol was led to its use in phthisis from these facts. He found in a factory at Bellegarde, in a room where sulphur was used, a number of consumptive women who refused to work elsewhere, because they always felt better in this room.

He had a large and closed room fitted up; in one corner he had a small brazier in which was sulphur slightly moistened with alcohol, and in the other corner the patient was placed, standing erect and taking deep respirations. Soon the effects of the sulphur were felt, and then the patient continued inhaling until chemically prepared paper in the room showed the lead reaction. At times, when the fumes of the sulphur were too strong, the windows were opened for a short time. To make the inhalations less irritating, a little benzoin or powdered opium may be added to the sulphur. In a little while the patient becomes accustomed to the fumes. These inhalations were practised in the morning and evening, on an empty stomach, and were followed up by exercise in the open air. Medicated inhalations were also used. Sixty-six tuberculous patients were treated in this way, in all of which an examination of the sputa showed the presence of the tubercle bacilli. Thirty of these, who were very ill, had their disease arrested so that the sweats and fever disappeared, the appetite and weight increased, and the bacilli disappeared. The lungs cleared up, and the caseous deposits became fibrous and innocuous. This state of things continued for a year and, no bad symptoms returning, they were considered cured. Many of the others were so far advanced in the disease, and took the treatment so irregularly, that they did not show the same improvement.

M. Dujardin-Beaumetz feeling convinced that there is something in this method of treatment, has fitted up a room in the manner above described, and makes the patients inhale the sulphurous fumes, letting in air from time to time to make it more bearable. In using the fumigation, a lamp or sulphurous "candle" is employed. The lamp increases the amount of CO_2 in the room, but M. Dujardin-Beaumetz thinks this causes the gases to be taken up more quickly. In the small number of patients treated (only seven), he has had excellent results, and he expects to make another report when a larger experience justifies it.

His conclusions are that it is not as good as the iodide of potassium in syphilis, but he thinks it is a cure for many cases. It is not only effective in stopping the trouble, but it acts well in ameliorating the bad symptoms when a cure is not possible. The French are so intensely enthusiastic over everything that seems to promise good results, that they are apt to rush into print before their theories are fully justified by facts. This treatment can, of course, only be carried on in hospitals, and it is to be hoped that equally good reports may be heard later, and that it may not share the fate of the rectal injection treatment.

SALICYLATE OF MERCURY IN SYPHILIS.

THERE is probably no disease which responds quicker to treatment than syphilis in most of its forms. In the earlier stages, particularly, mercury, as a salt, has generally been very effective. Of late, salicylic acid, combined with a base, has been the fashionable remedy for a variety of affections.

The latest combination is the salicylate of mercury, which Dr. Sylva Aranjo, of Rio Janeiro, has been using with some success in certain obstinate cases of syphilis. In a letter to the *Bulletin Général de Thérapeutique*, he gives some details of his method. The salt is formed by the double decomposition of the salicylate of potassium with the acid nitrate of mercury. He began by administering one milligram in a pill in milk every morning, and if this was borne well, one, morning and evening, until it was given three times a day, and increased to such doses that the patient took in the end twenty-five milligrams during the day. It was also used externally as an ointment in the strength of fifty centigrams to one gram to thirty grams of vaseline. As an injection for blennorrhagia, it is employed in the strength of ten grams to two hundred and fifty grams of water, with enough of carbonate of sodium to make a solution. The advantages which Dr. Aranjo claims for this drug, are:

1. It is supported easily by the stomach without any bad effects.
2. It does not cause mercurial stomatitis.
3. It acts much more promptly than the other salts of the same base.
4. Used externally, it has a curative effect on the mucous patches and the other ordinary syphiloderms.
5. In many of the parasitic diseases it is of great advantage.

6. It is very effective where other forms of mercury have no effect.

In one case Dr. Aranjo had used without effect the protiodide, the bichloride, the biniodide, the tannate, and phenate, as well as the iodides of potassium and sodium.

7. It is of use in lepra.

8. As above stated, it forms one of the many injections for blennorrhagia.

Also in catarrhal and granular conjunctivitis, as a collyrium, in the following prescription it has been very effective:

℞.	Salicylate of mercury	0.50
	Distilled water	30
	Carbonate of potassium	q.s.

M. For eye-wash.

RECENT STUDIES OF THE TYPHOID BACILLUS.

Dr. Edwin Klebs, in his "Allgemeine Pathologie," records the work that has been done in studying the natural history of the typhoid bacillus up to, and including, the year 1886. Naturally he inclines to side with those who believe in the pathogenic function of this bacillus. But further observations were needed to satisfy most persons, and such observations continue to be made.

In 1886 Fraenkel and Simmonds claimed to have produced true typhoid fever in guinea-pigs and rabbits by inoculations of pure cultures. The same authors report the continuation of their work in 1887 (*Zeitsch. f. Hygiene*, i.). They found, as had Sirotinin and Brieger, that the typhoid bacillus, in its growth in certain media, developed poisons which, when injected into animals, produced morbid phenomena. They reassert the correctness of their experiments, by which the anatomical appearances of typhoid fever were produced in animals by injection of the micro-organisms.

Dr. Sirotinin (*Zeitsch. f. Hygiene*, i.) obtained pure typhoid cultures; then having sterilized these, or by filtration removed the organisms, he injected the cultures so treated into the veins and peritoneum, and also gave some of the material by mouth. He obtained the same pathological phenomena by this method as he did when the living organs were injected. Furthermore, the severity of the symptoms stood in definite relation to the amount of the culture-material used. Hence he thinks that the symptoms produced by the inoculation of typhoid bacilli are due, not to "infection," but to intoxication by ptomaïnes. In further support of this, he asserts that the cultivated bacilli do not notably multiply in the blood (this opinion is directly contradicted by Fraenkel and Simmonds). The poisonous ptomaïne produces clinical symptoms and pathological changes much like those of typhoid fever. The phenomena are most intensely marked in dogs, next in rabbits, and barely at all in guinea-pigs.

Beumer and Peiper (*Zeitsch. f. Hygiene*, i.) confirm the view of Sirotinin that the consequences of intravenous or intraperitoneal injections of typhoid cultures varies with the amount of the substances used, and that, therefore, the morbid symptoms are due to a poison, and not to a multiplication of the bacilli. In a subsequent communication, the authors say that the symptoms of typhoid are due, primarily, to an intestinal mycosis, the micro-organisms secreting a poison which is the cause of the phenomena of the disease. They suggest the possibility of securing immunity against the disease by inoculating attenuations of the active poison.

This virus was separated by Brieger, and analyzed chemically. The formula given is $C_7H_{17}NO_2$, which combination may be assumed, provisionally, to be the chemical equivalent of typhoid fever.

Dr. C. Seitz, of Munich, has reported some results of bacteriological studies of typhoid fever (München, J. A. Finistertin, 1886, *Centralbl. f. Klin. Med.*, 1887, No. 15). His observations are, in the main, confirmatory of those of others. He failed in eleven cases even to find the specific bacilli in the papules or in the blood of typhoid-fever patients. He did not always find them in the dejections (eight times in nineteen trials in six patients). In the urine the bacilli were found only in those cases in which there was albuminuria.

Wiltschur (*Wratsch*, 1886, No. 25; *Centralbl. f. Klin. Med.*, 1887, No. 15) and G. Lepidi-Chioti (*Giorn. intern. delle Sc. med.*, 1886, fasc. 4) have reported results of observations upon the methods of cultivating, staining, etc., and of diagnosticating the typhoid bacillus. Their work has but a purely technical interest.

STOMATITIS IN MILK.

The origin of aphthous stomatitis of adults and follicular stomatitis of infants has always been supposed to lie in a disordered digestion. Recent researches by David, reported in the *Archives de Médecine*, seem likely to throw important light on the pathology of the affection. He believes that it is identical with a similar disease of domestic cattle, cows and sheep especially. It is infectious and contagious. The latter property would more likely cause the disease in adults; the former through the medium of the milk in children.

To support this view, David adduces four arguments: *First*, the macroscopic and microscopic appearance of the human and bovine diseases are identical; *second*, he cites cases of the actual transmission from the animal to man, and the reverse; *third*, an epizoötic of the one is paralleled by an epidemic of the other; and, finally, he has actually observed the disease in man within three or four days after taking milk from animals affected.

Thus we have a specific contagium, the habitat of which is the mucous membrane of the mouth and upper portions of the gastro-enteric tract. How the milk becomes affected is a difficult question to decide. Many cases of stomatitis in children are characterized by constitutional symptoms of no little severity. They require general, as well as local treatment. We regard the malady, practically, as a general one. On this principle it is easy to account for milk infection. As David reminds us, cows very frequently lick the udder, and this habit affords easy transmission of the affection from the seat of its development to the source of the milk. Of a similar bearing is the sucking of the udder by calves in whom the disease may have developed.

If this new view is correct, inspection of dairies by State veterinarians is in order. It would not be necessary for animals to be killed; but during the prevalence of an epizoötic the milk of the infected herd should be destroyed. The possible danger of contagion is another argument for the boiling of each day's supply of milk, whereby the germs would be destroyed, or, at least, rendered powerless.

This view of the disease does not entirely banish the causative relation of digestive disorders. They may still be regarded as strongly predisposing circumstances.

THE HARM OF MODERATE DRINKING.

It is very well known that hard drinking surely kills; it is equally well known that moderate drinking is usually injurious. There are, however, two forms of the latter habit: in one, the individual drinks moderately and only at his meals, in the other, he drinks over a bar, taking a "nip" of whiskey, a "cocktail," "fizz," etc., in accordance with the idiosyncrasy of his palate, his geographical location, or personal associations. These last-named indulge in what our continental brethren call "nipping" or "pegging," and the practice of nipping has been apparently shown by Dr. Harley and others to be injurious to health and life.

Dr. Harley gives the following telling statistics:

Death-rate of men between the ages of twenty-five and sixty-five.

Men Exposed to the Temptations of "Nipping."

	Liver diseases.	Urinary diseases.
Commercial travellers	61	44
Brewers	96	55
Innkeepers, publicans, vintners, barmen, and waiters	240	83

The comparative death-rates of men of the same age engaged in other industries, not exposed to the temptation of "nipping," are, again, as follows:

Death-rate of Men not Exposed to the Temptations of "Nipping."

	Liver diseases.	Urinary diseases.
Gardeners and nurserymen	18	39
Printers	28	30
Farmers and graziers	41	31
Drapers and warehousemen	35	37

In addition to the above Dr. Harley cites the following statistics of beer, which apply to Prussia:

Probable Duration of the Life of Men.

Age.	In the liquor trade.	Not in the liquor trade.
25	26.23	32.08
35	20.01	25.92
45	15.19	19.92
55	11.16	14.45
65	8.04	9.72

Further statistics are given, showing the extraordinary excess of mortality from liver disease among innkeepers, bar-tenders, vintners, waiters, and publicans, as compared with persons in other occupations. The ratio is as six to one.

To all this it may be said, on the other hand, that nothing lies like figures, and that, after all, the mortality-rate is not greater, for example, in a whiskey-drinking country like Scotland, than in presumably temperate regions like certain States of New England or the West. It is more than probable that Dr. Harley's figures point to the truth; but the question rises, in view of the pretty even range of mortality in countries of temperate and "nipping" habits, whether, if liquor is taken away, some other death-producing agency does not set at work? We believe that the medical profession must, at any rate, accept the fact that "nipping" shortens life.

OUR NEW LABORATORIES.

Within the past three years, practically, four new medical laboratories have been opened in this city and immediate vicinity. Their establishment has been heralded as marking a new era in medical study, and so much has this idea been harped on that we may forget one very important fact. A laboratory established is a great thing. A laboratory properly endowed is a much greater thing. For suitable endowments, therefore, we plead.

It cannot be denied that, under the present circumstances, the laboratories are virtually inaccessible to many medical students. The expense of running such institutions is large. College fees—those absolutely necessary—are a burden to many, and to increase them by laboratory charges is outside the ability of many a man, however ardently he may long therefor. The supply of hay is ample, but it is too high up for the sheep to reach it.

Of far greater importance than the mere subject-matter of a college course, are the habits of study which it should inculcate in every man. Very few develop a taste for scientific work after graduation, unless the seed has been planted in their undergraduate days. The habit of careful observation is better cultivated by laboratory work than in any other way.

Only a small percentage of the students in our colleges work in the laboratories. The courses in them, though recommended, are not required. Probably the question of expense is the great deterring factor. Yet, in all of our institutions, a fee is absolutely necessary, in order to render the practical department self-supporting. The last three years have witnessed a grand departure in the matter of elevating the standard and broadening the scope of medical education; but unless endowments are forthcoming the new facilities will be accessible to only a comparative few. The regular college fees are now about as high as is proper. We regret to believe (as we are compelled to) that in some cases the return for the money paid is so unprofitable from an educational point of view. Endowments we must have. Will not the benevolent citizens of New York thus supplement the good work already done?

INEQUALITY OF THE PUPILS IN HEALTH.

In many diseases of the encephalon inequality of the pupils is regarded as a sign of considerable diagnostic value, this condition being thought, indeed, by many, to be pathognomonic of cerebral disease. That this is, however, not always reliable, is shown by the results of a number of examinations of healthy persons made by Dr. G. C. Ivanoff, and reported in *Vratch*, No. 7, 1887. His investigations were conducted without the aid of instruments of any kind, the differences being estimated solely by the eye. The subjects of the investigation were peasants from the government of Novgorod, serving in the army, and numbered 134. Of this number the pupils were equal in only 12, or about 9 per cent.; in 73 instances, or 54.5 per cent., the left pupil was larger than the right; and in 49, or 36.5 per cent., the right pupil was the larger. In most of these cases there was also asymmetry of the two halves of the face, the left side being larger than the right in 99 individuals, the right being the larger in 32. Although the totals in these two sets of figures corresponded in a general way in as far as the left side of the face was more commonly the larger, and the left pupil was the more dilated, yet there seems to have been no real connection between the two, as there were many cases in which the left side of the face was the larger, while it was the right pupil that was the more dilated, and *vice versa*.

From the results of this series of examinations Dr. Ivanoff came to the rather hasty conclusion, considering the comparatively small number of cases, that equality of the pupils, as well as of the two halves of the face, is of not very frequent occurrence. And he thought that the inequality so often present was due, doubtless, to the unequal development of the two cerebral hemispheres.

In the *Revue Internationale des Sciences Médicales*, No. 1, 1888, Dr. Martel relates an instance of intermittent inequality of the pupils. One day the left pupil would be widely dilated, while the right was normal, and the following day, or perhaps several days later, the right pupil would become dilated, while the left returned to its normal size. There was no other trouble with the eyes, except a slight degree of exophthalmia. This was not a case of hippus, a condition allied to nystagmus, in which contraction and dilatation of the pupils follow each other at very short intervals, for the changes occurred slowly and never at intervals of less than twenty-four hours.

TOLSTOÏ ON THE MEDICAL PROFESSION.

The literary world is suffering with an intense *furor* Tolstoï-icus, if we may so express it, and the words that drop from the lips of the noble Russian or flow from his pen are receiving a wide and profound attention. Hence, we venture to comment upon a recent utterance of Tolstoï regarding the condition and tendency of modern medicine. Tolstoï does not believe in science, and he thinks in particular that medical science is progressing in an entirely wrong direction.

"Medical science," he says, "is entirely arranged for the wealthy classes, and it has adopted for its task the healing of the people who can obtain everything for themselves; and it attempts to heal those who possess no superfluity, by the same means. The physician has studied with celebrities in the capitals, who only retain patients who can be cured in the hospital, and who, in the course of their cure, can purchase the appliances requisite for healing, and even go at once from the north to the south, to some baths or other. Science is of such a nature that every rural physician laments because there are no means of curing working-men, because he is so poor that he has not the means to place the sick man in the proper hygienic conditions; and at the same time this physician complains that there are no hospitals, and that he cannot get through with his work, that he needs assistants, more doctors and practitioners."

What the physician, according to Tolstoï, should do, would be to join the toiling masses, "live under the same conditions and exactly as they do;" then he will be able to apply his knowledge to the healing and the hygiene of the laboring people.

Tolstoï's idea seems to be that the physician should become a kind of devotee, living in tenement-houses on bread and beer, perhaps, teaching those about him how to live properly, and treating their infirmities as they arise.

This is a picturesque view of medical life; but it would be very difficult to put it in practice. The idea that the working-people need sanitary missions is an old one; the idea that they need a charitable medical service is still older, and is practically carried out in all civilized countries. But the idea that the two kinds of work should be done by the doctor alone is certainly new. Medical science, out of Russia at least, is tending more and more to make it possible for the poor to get their treatment free, and to make the treatment of those who have money more expensive. Hence, while Count Tolstoï's reflections may apply in his own land, they will hardly do for the United States. The distinguished novelist having no little Tolstoïwitches to support, can afford, perhaps, to go, as is his custom, and weed the onions for four hours daily. But the average doctor has personal duties and encumbrances which prevent his indulging in this form of altruism.

PNEUMONIA IN GENERAL PARALYSIS.

Diseases of the lungs are responsible for a large proportion of the deaths in general paralysis of the insane, and of these pneumonia is one of the most common. According to some clinical and experimental studies made by Drs. Bianchi and Armanni, and communicated by them to the Royal Medico-Chirurgical Academy of Naples (*Rivista Clinica e Terapeutica*, February, 1888), this pneumonia is peculiar, and differs markedly from the forms usually encountered. The following are the chief points brought out by the authors in their communication:

1. Pneumonia occurring in general paralysis of the insane differs from the ordinary forms—croupous, hypostatic, and broncho-pneumonia—met with in those of sound mind.

2. It was found constantly associated, in all the cases studied, with degeneration of the pneumogastric nerves, and was produced experimentally in animals by resecting the vagi in them.

3. Its immediate causation may be the entrance of the buccal secretions and of fragments of food into the air-passages. But doubtless the lesion of the pneumogastric nerve predisposes to it, by means of a rather complex mechanism, in which figure, as the chief factors, paralysis of the larynx and of the œsophagus, disturbances of innervation, and, perhaps also, vaso-motor paralysis, and that of the bronchi.

A micro-organism has been found in certain cases of vagus pneumonia, and inoculation experiments with it on rabbits have excited pulmonary inflammation; but concerning this bacillus the authors were unprepared to give an opinion. They wished simply to emphasize the more than coincidence of the occurrence of pneumonia with evident degeneration of the pneumogastric nerve.

MERCURY IN THE CURE OF MERCURIAL STOMATITIS.

Somewhat in the nature of a paradox seems to be the assertion that the best remedy for the cure of sore mouth caused by mercury is mercury. Yet such is the claim made in the *Rivista Clinica e Terapeutica* for February, 1888, by the director of the journal, Dr. E. De Renzi, and which he supports by the recital of two cases. The first case was that of a man, thirty years of age, who was admitted to hospital for treatment of some tertiary manifestations of syphilis. He was put upon mixed treatment of iodide of potassium and bichloride of mercury, the latter by subcutaneous injection. He made use at the same time of a mouth-wash of chlorate of potassium. After the seventh injection he began to show symptoms of stomatitis. A mouth-wash consisting of a solution of corrosive sublimate was then given him, and in four days the gingivitis had entirely disappeared, although the mercurial injections were continued. The second case was similar, except that the stomatitis was much more severe; ulcers being present on the gingival and labial surfaces, and the breath being very fetid. The specific treatment was discontinued, a mouth-wash of bichloride of mercury was prescribed, and in four days the fetor of the breath had disappeared, and the ulcers were nearly healed.

Dr. De Renzi explains the good effects observed in these cases by assuming that mercurial stomatitis differs in no way from any other form of sore mouth, except in its predisposing cause. He thinks that the mercurial treatment does not produce stomatitis directly, but only by modifying the nutrition of the buccal mucous membrane so that the micro-organisms directly instrumental in exciting the inflammation effect an easy lodgement and find there a soil well adapted to their growth and multiplication. The sublimate mouth-wash destroys these microbes, and thus cures the disease. The strength of the solution employed is three grains and three-fourths to two pints of water, of which one pint is consumed daily in rinsing the mouth and bathing the inflamed gums.

SECRETION OF MILK IN THE NON-PREGNANT CONDITION.

Quite a number of cases are upon record of non-pregnant women, either married or unmarried, who have had a more or less abundant secretion of milk, or of a milk-like fluid, from the mammary glands. In some of these it was mentioned that there was at the same time some uterine or ovarian trouble present, but the coincidence has not been noted with sufficient frequence to establish the rule. Dr. Otto Engstrom, writing in the *Finska Läkaresällskapets Handlingar*, No. 10, 1887, adds five hitherto unreported instances which have come under his own observation. The first was a married woman, thirty-six years of age. She had had a secretion of milk for over three years. A large dermoid cyst of the ovary had been removed, but the operation was not followed by a cessation of the secretion. In the second woman, in whom there was a slight endometritis only noted, pressure upon the breasts caused a few drops of a fluid resembling colostrum to exude. The third case was that of an unmarried woman, thirty-four years of age, who had marked anteflexion of the uterus and endometritis. There was a slight secretion of a yellowish fluid from the breasts, which disappeared after a cure of the uterine trouble. In the fourth instance there was retroflexion with endometritis, and, as in the preceding case, the secretion of a milk-like fluid by the mammary glands ceased upon the rectification of the uterine malposition. The fifth woman was married, twenty-six years of age, and suffered from a complication of uterine disorders. There was a secretion of milk from the right breast, which decreased markedly in proportion as the inflammation of the uterine structures was reduced.

These cases, which we have been unable to more than refer to, possess a double interest. They will go to strengthen the opinion of those who regard the mammary functions as regulated, or at least started, by reflex uterine influences. They are also of interest from a medico-legal point of view, showing that the presence of a slight mammary secretion is not indubitable evidence of recent pregnancy or child-birth.

URINARY PARAPLEGIA.

Various writers have described, under this title, certain paralyses occurring without evident cause in individuals suffering from some affection of the kidneys or of the urinary organs. Others, again, have denied the existence of an affection of this nature, maintaining that the paraplegia, when present, was due to actual lesion of the cord or peripheral nerves. In the *Revue Générale de Clinique et de Thérapeutique* of December 22, 1887, Dr. Étienne contributes a critical review of the supposed cases of this nature reported by writers from the time of Graves to Charcot, and rejects most of them as inconclusive. He accepts a few, however, and, weighing all the evidence presented, inclines to the belief that urinary paraplegia, so-called, though rare, is nevertheless occasionally met with. The following are the conclusions formulated by him in this paper:

1. In the course of an affection of any part of the urinary apparatus there may supervene disturbances of sensation or of motion in the lower extremities.
2. The demonstration of the possibility of these disturbances, and the theory of their production, were established at a period long in advance of any conclusive clinical evidence of their existence.
3. Instances of undoubted urinary paraplegia are very rare.
4. In the greater number of cases of urinary paraplegia, cited by different authorities, the lesions of the urinary apparatus, far from being the point of departure of the nervous disturbances, were in reality caused by them.
5. These reflex disturbances, when they occur in the course of some affection of the urinary organs, are seen most frequently in neuropathic individuals who are already predisposed to the occurrence of nervous troubles.

A NEW INTERPRETATION OF NATURAL SLEEP.

Certain disorders of sleep, somniloquy and somnambulism, bear a striking resemblance in many respects to hypnotism, yet one usually looks upon the latter as something wholly distinct from normal sleep. Dr. Maurice Vincent, writing in the *Gazette Hebdomadaire des Sciences Méaicales ae Bordeaux*, of January 29, 1888, expresses his belief in the existence of an intimate relationship, physiological and psychical, between these two processes. In hypnotic sleep, he says, the person fixes his attention upon some object, and after a longer or shorter time he gradually loses the power of association of ideas and falls asleep. In normal sleep this fixation is not generally noticed, yet it exists, he believes, and can often be clearly demonstrated. Thus, many people, it is known, can sleep only by fixing their thoughts on something. One figures to himself an endless line of sheep jumping over a low-barred gate; another sees the drops falling one by one in rapid succession from the tip of a long icicle; a pious soul will tell her beads, and so get the sleep she prays for; another counts from one up to the point where sleep interrupts him, and so on. It is true that physical fatigue leads more rapidly to slumber; but so, says the author, is hypnotic sleep induced more easily in those whose physical powers are depressed. In hypnotism there are two persons concerned, the experimenter and the subject, and in natural sleep there is but one, who, as it were, hypnotizes himself. Sleep might therefore be called, by those accepting M. Vincent's theory, auto-hypnotism, were they not satisfied with its present designation.

PROFESSIONAL VISITS.

The number of professional visits which a physician can make in a day has of late been the subject of some discussion. A New England doctor is credited with having made thirty-five calls in twenty-four hours, besides attending three confinements. The West produces something far ahead of this in the person of a Sacramento doctor who claims to have made one hundred visits a day, besides attending four confinements! The *Medical Age* promises something from Detroit that will even surpass the hyperkinesis of Sacramento, and we await the anecdote with eagerness. It appears to us that the conscientious physician can hardly make more than twenty or thirty calls a day and do his patients justice. Naturally much depends upon the distance which one is obliged to travel. But allowing fifteen minutes for travelling and fifteen more for the briefest average of visits, it will be seen that a doctor must work fifteen hours a day to make even thirty visits. And fifteen hours' work in these days turns even conservative knights of labor into raving anarchists.

It has been related that certain physicians in this city have habitually made forty to sixty visits daily; but inquiry has shown that the story is false, or the physicians have been homœopaths.

We trust that there will be no ambition to break the record in number of daily visits. It is quality, not quantity, that is needed.

The New Local Anæsthetic Erythrophlaline has been tested by Dr. Felix Loewenhardt, who finds that it does produce anæsthesia, but is quite irritating. Karewski has used it in neuralgias with success. Schöler has made experiments with the drug regarding its influence upon the eye. He finds that it produces conjunctival anæsthesia slowly (after five minutes), which lasts for several hours. There develops some weakness of the lids, and the patient sees colored rings of light, but the third nerve and the sympathetic do not seem to be affected. The action of the drug suggests in some respects that of aconite.

We regret to chronicle the fact that a highly esteemed and accomplished physician, Dr. F. M. Hamlin, of Auburn, N. Y., has become a victim to the morphine and cocaine habit, and has had to be removed to the Utica Asylum.

News of the Week.

The Tennessee State Medical Society meets at Knoxville on April 10th.

The Twentieth Annual Session of the Texas State Medical Association will be held in the city of Galveston, beginning on the fourth Tuesday in April, 1888.

The Miami Medical College held its Twenty-eighth Annual Commencement at Cincinnati on March 9th. A class of twenty-two was graduated.

The Mississippi State Medical Association meets at Jackson the third Wednesday of April.

Our prophecy some months ago that there would soon be a society of gastric specialists is not yet fulfilled. But the penumbra of such an institution has fallen upon Paris, which has just organized a Stomatological Society, for the study of the diseases of the mouth, teeth, and adjacent parts. After stomatology will come œsophagology, and then by easy stages gastrology and enterology.

The Gynecean Hospital is the uniquely qualified title of a new institution in Philadelphia, intended, we presume, for the treatment of the "gynecea," a name which used to be applied to the catamenial discharge as well as to the diseases of women.

The Action of Heart Tonics.—Digitalis and strophanthus especially stimulate the heart muscle; convallaria stimulates the heart muscle and nerves; caffein chiefly stimulates the cardiac nerves (Rumino and Ferranini).

Bloomingdale Asylum.—The property-holders of the Morningside Park Association ask for a report to the Legislature recommending: "1. That a law be passed subjecting the Asylum to visitation by the Board of State Charities. 2. That all real estate of the society at Bloomingdale, outside of the boundary of One Hundred and Sixteenth Street, One Hundred and Twentieth Street, Tenth Avenue, and the Broadway Boulevard be made subject to taxation. 3. That power be given to the Board of Street Openings in said city to open One Hundred and Fifteenth and One Hundred and Sixteenth Streets through the Asylum grounds whenever, in their judgment, it may seem proper. 4. That a limited time, not exceeding two years, be given to the society to remove the lunatics at Bloomingdale to quarters outside of the city. 5. That, after the Asylum shall be removed, like power be given to the Board of Street Openings to open One Hundred and Seventeenth, One Hundred and Eighteenth, and One Hundred and Nineteenth Streets through the Asylum grounds."

The Quarantine Bill, which places the Health Officer of the Port on a salary of $10,000 a year, has become a law.

It is announced in the daily papers that Dr. William S. Bryant, of Boston, has made a great anatomical discovery. This consists in his finding that there are valves in the portal and mesenteric veins, during infant life, in seventy-five or eighty per cent. of cases. These disappear as the child grows.

Dr. William C. Spencer, United States Army, died of pneumonia at Fort Trumbull, Conn., on March 22d, after two days' illness. He was appointed Assistant Surgeon in 1861, promoted to Captain and Assistant Surgeon in 1866, and to Major and Surgeon in July of the same year. He was breveted Lieutenant-Colonel March 13, 1865, for faithful and meritorious service during the war. He was fifty years old.

Dr. O. W. Holmes' Medical Books.—Dr. Oliver Wendell Holmes has presented to the Medical Library, Boylston Place, his very valuable and extensive collection of medical books.

The Memphis Hospital Medical College held its Eighth Annual Commencement on March 1st, and conferred degrees on fifty-four graduates.

The Medical Department of the Arkansas Industrial University held its Commencement March 1, 1888, and graduated twenty men as physicians.

The Baltimore College of Physicians and Surgeons held its Annual Commencement on March 15th, and graduated a class of seventy-seven.

The State Medical Law of Virginia has recently been amended by the Legislature, and it is believed made still more efficient. No one can now practise medicine in Virginia without passing an examination and getting a licence from the Medical Board. The diploma-giving and licensing powers are separate.

The so-called Cancer Bacillus.—Dr. Emil Senger has made a series of bacteriological experiments (*Berl. klin. Woch.*) to test the truth of Scheurlen's alleged discovery of a specific bacillus of cancer. He tried to obtain cultivations in sterilized gelatine, agar-agar, blood-serum, and ascetic fluid, making sixty-five trials in all, but with no success whatever. He concludes, therefore, that the bacillus described by Scheurlen is not characteristic of cancer.

The Emperor of Germany.—Whatever may be thought regarding the nature of the present German Emperor's illness, there can be but one opinion as to the great skill, tact, and firmness shown by Sir Morell Mackenzie in his management of the case. We learn that the order of the Star of Hohenzollern is to be presented to him in recognition of his services. As a contemporary has truly said, many a man has been made a duke for less than Sir Morell has done.

Tincture and Powder of Pyrethrum Roseum are said by Dr. Jaeger, of Singapore, to be a sure prevention of, and relief from, the stings and bites of insects. New Jersey can take notice.

A very typically clumsy and thoroughly Teutonic refinement in medical art has been put forward by Dr. Wachsner in the *Deut. Medizin Wochenschrift*, No. 51. His claim is that the application of the induced electrical current for several minutes after the hypodermic injection promotes absorption and prevents the formation of abscesses. That such is the case we can well imagine to be true, but that the battery is specifically more efficient than careful massage is doubtful; and the addition of an electrical battery as an annex to the hypodermic syringe makes a cumbersome combination.

Leprosy not Spreading in Minnesota.—The State Board of Health of Minnesota gives out the statement by Dr. Grondold, of Norway, Minn., that "no case of leprosy has ever originated in Minnesota by contagion, and that of all the children of lepers living here not one has exhibited any signs of the disease."

The Illinois State Board of Health has suffered a second defeat in its efforts to enforce the law against unlicensed practitioners of medicine. The defendants were T. G. Gilfillan and T. W. Gray, who operated a medicine lodge at Kirkwood. Their defence was the emergency clause of the law. The jury disagreed.—*Sanitary News.*

Thallin in Gonorrhœa.—Goll claims that injections of two to two-and-a-half per cent. solutions of thallin sulphate will cure almost all cases of gonorrhœa in a few days. Two to four injections must be made daily.

Swedish Movement Cure.—There seems to be just now a general immigration of Swedish masseurs into this country. Few months pass without the receipt of the card of some new and highly indorsed arrival. We beg to warn Scandinavia that this thing may be overdone.

The Decoction of Thyme (*Thymus Vulgaris*) is claimed by Dr. J. B. Johnson, of Washington (*Medical and Surgical Reporter*), to be a most satisfactory and useful drug in the treatment of whooping-cough.

Property in Clinical Lectures.—The question as to whether a medical student or medical reporter can report and have published clinical lectures delivered at medical colleges has been recently discussed as though it were a new one. It has given rise to much trouble in this city and elsewhere in times past. The law in the matter, as laid down in the case of Abernethy *vs.* Hutchinson, and Nicols *vs.* Pitman (quoted by R. V. Rogers, Jr.) is that pupils and others admitted to hear the lectures of medical men can only take down such lectures for purposes of their own information, "and cannot publish the lectures for profit without the consent of the lecturer."

Dr. Hartwig's name was not properly printed in our last issue.

Dr. Lippe a Count.—We learn from German exchanges that Dr. Adolph Lippe, a homœopathic physician of Philadelphia, who died on January 23d, was a German count, who preferred homœopathy in Philadelphia to the prince business in his native land.

Association of the Alumni of the Long Island College Hospital.—At the annual meeting, held March 7, 1888, the following officers were elected for the ensuing year: Charles E. De la Vergne, M.D., '78, *President;* F. H. Colton, M.D., '64, *Vice-President;* H. Messenger Ayres, M.D., '80, *Secretary;* Robert L. Dickinson, M.D., '82, *Corresponding Secretary;* Charles N. Dixon Jones, M.D., '82, *Treasurer.* The Alumni Prize of one hundred dollars was awarded to A. H. Buckmaster, M.D., '83, for an essay entitled "The Galvanic Treatment of Fibro-myomata: An Experimental Research." The Association also makes honorable mention of the essay by Charles N. Dixon Jones, M.D., '82, entitled "Etiology and Pathology of Rachitic Deformities, with Report of One Hundred and Two Osteotomies without Suppuration."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PRACTICE OF MEDICINE.

Stated Meeting, February 21, 1888.

R. C. M. PAGE, M.D., CHAIRMAN.

DR. GEORGE R. ELLIOTT was elected Secretary in place of Dr. George B. Fowler, who had resigned.

DR. FREDERICK A. BURRALL presented a specimen of chylous urine obtained from a lady seventy years of age. She had had attacks of chyluria for the past forty years. She had lived in the South until within the past twenty years. No filariæ had ever been found in the urine. The patient had done better under a nutritious diet and tincture of the chloride of iron than under any other treatment.

DR. A. D. ROCKWELL then read a paper on

THE CUMULATIVE ACTION OF THE GALVANIC CURRENT, WITH ESPECIAL REFERENCE TO CERTAIN FORMS OF PARALYSIS AND EXOPHTHALMIC GOITRE.

(It will appear in THE MEDICAL RECORD.)

DR. W. R. BIRDSALL agreed with what Dr. Rockwell had said respecting the use of the strong galvanic current in infantile spinal paralysis. It is certainly possible to do harm by using too strong a current rapidly interrupted; yet he believed that the most serviceable effects are obtained by the interrupted galvanic current properly applied. We should watch the effect and avoid rapid exhaustion of the muscle. The current should be strong, but it should not be used to the degree of causing muscular weakness.

In exophthalmic goitre and some other cases of functional disturbance referred to in the paper, Dr. Birdsall had obtained better results from the uninterrupted current.

DR. HERMAN M. BIGGS then read a paper on

SOME OBSERVATIONS ON AORTIC ANEURISMS, WITH REPORT OF CASES AND AUTOPSIES.

He believed aneurismal dilatation of the aorta to be a more common affection than is generally supposed, and the object of his paper was to record a series of thirty-one cases, with two cases of rupture of the aorta, and to call attention to some features of the affection which he thought have not been sufficiently emphasized. He was indebted to Deputy Coroner Jenkins for the opportunity to see many of the cases, for it is in the service of the coroner that a large proportion of this class of cases are seen. His paper went to show how frequently the affection exists without producing any symptoms, or at least symptoms marked enough to cause the patient to consult a physician, or characteristic enough to make a diagnosis possible by physical examination.

Of the series of 33 cases, 29 were of either fusiform or circular dilatation of the aorta, with death from rupture or other causes in 28; 1 is still living. Of the remaining 4, 2 were dissecting aneurism, and 2 were simple ruptures of the aorta. An autopsy had been held in 32. Twenty-five were of the arch of the aorta and of the thoracic aorta; 4 were of the abdominal aorta. Twelve were of the ascending portion of the arch; of these about one-third were in the sinuses just above the aortic valves; the remainder were situated higher. Three were of the ascending and transverse portion; 1, of the transverse portion alone; 4, of the transverse and descending; and 5, of the thoracic aorta. As to the character of the aneurism in those cases in which only one aneurism was found, 20 were saccular, 4 were simple fusiform, and 2 were dissecting. In 5 cases the aneurism was multiple, 2 of which were fusiform and saccular, and in 2 there were two and five saccular aneurisms respectively. In the fifth there were saccular and fusiform aneurisms.

Sixteen of the aneurisms ruptured into the pericardium, one each into the right pleura, œsophagus, left bronchus, left pleura, left lung, left bronchus and lung, spinal canal, and retro-peritoneal tissue; two into the left pleura and lung; and three into the peritoneal cavity. In two cases death occurred from some other cause without rupture. The average of those whose age was obtained was forty-three and one-half years. Eight were in females; 25, in males. The females were all domestics; of the males all but 6 were engaged in some laborious occupation. The history was in many cases imperfect. In only 5 was there evidence of syphilis. An alcoholic history was given in 8 cases, and was probably present in many more.

In the 25 cases of thoracic aneurism in which rupture occurred a history suggestive of aneurism was present in only 11. In 7 of these the aneurism was situated at or beyond the junction of the ascending and transverse aorta. Thus in 9 out of 12 aneurisms situated wholly on the ascending portion of the arch there was no history suggestive of aneurism. The aneurisms of the abdominal aorta were all made out during life.

In almost every case in which a second person was present, death was almost instantaneous. In a number of cases there were several attacks of hæmoptysis, some time before the fatal hemorrhage occurred, and in every instance the hemorrhages were ascribed by the physician in charge to pulmonary tuberculosis, but the autopsy revealed no such lesion. In three cases rupture occurred first into the lung, and then blood found its way into the pleural cavity. In all of these pulmonary hemorrhage occurred before and at the time of death, and in two a large amount of blood was found in the stomach, having entered by way of the pharynx and œsophagus. In ten cases death occurred instantly, without warning. In others the subjects were found dead. Contrary to what would *à priori* be supposed, death occurred in but few instances during severe muscular exercise. The site of the aneurisms as regards frequency corresponded pretty closely with the site of greatest strain on the aorta.

Primary rupture of the aorta, without previous dilatation, is of infrequent occurrence. In such cases there is usually thinning of the coats. In his first case the patient was a female suffering from tubercular peritonitis. The aorta was the seat of endarteritis, and the rupture occurred about one and a half inch above the aortic valve, where a calcific plate had broken through the superficial layers of the intima. The second case was that of an iron-worker, and the rupture took place when he was going upstairs. A physician was sent for, who prescribed for him, and told him he would soon be well, but death resulted a few moments later. The autopsy showed the pericardium filled with blood, and a transverse rupture of the aorta, one inch in length, situated about an inch above the valves. At the point of rupture there was little change in the coats, except that they seemed thin.

Dissecting aneurisms differ from rupture of the artery only in the greater resistance of the outer coat. The history of one of his cases was like that of the one of rupture, except that death did not occur so early.

In commenting upon the cases, Dr. Biggs said he agreed with Dr. Jenkins that rupture of thoracic aneurism is one of the most frequent causes of sudden death. Such cases, however, are frequently classed among those of death from cardiac disease or cerebral hemorrhage. As to the pathology of aneurismal dilatation of the aorta, it had seemed to him that far too much emphasis had been placed on the influence of endarteritis and atheroma. These are not the changes which ordinarily or necessarily lead to dilatation, and in themselves, if they do not produce secondary changes in the media, are not followed by dilatation, at least in the aorta. The changes which precede the dilatation in the aorta are, in the majority of cases, situated in the middle coat, and seem to be degenerative rather than inflammatory. There is a granular degeneration and disappearance of the elastic fibres and fatty degeneration in the muscle-cells. When the process is slow there is a secondary new-growth of connective tissue, which Dr. Biggs regarded as a conservative process. After degeneration of the elastic fibres they are not reproduced, but their place is taken by newly formed fibrous connective tissue. Occasionally the process in the media is inflammatory in character, and is properly designated an endarteritis; but these cases are the exception rather than the rule. In these the adventitia is also often involved, and a dense round-cell infiltration is found around the vasa vasorum.

The etiology of aortic aneurism is somewhat obscure. He thought there could be no question about the influence of syphilis in the production of aneurisms, and there are many reasons for regarding this disease as the chief factor in the causation. The degenerative changes in the middle coat which precede the formation of aneurism are just such changes as would be likely to be produced by syphilis. A large proportion of cases of aortic aneurisms are found in a class of persons most likely to have been the subjects of syphilis. Very frequently, where an accurate history could be obtained, the patients were found to be syphilitics. Severe exercise can be productive of dilatation only when preceded by morbid changes in the coats of the vessel.

Dr. J. West Roosevelt thought that we are likely to get an erroneous idea of the frequency of these cases if we judge by the number which fall into the coroner's hands. Most of them are coroner's cases because in most of them death takes place suddenly. As to thoracic aneurism frequently being unattended by symptoms, this is not astonishing when we consider the cause of the principal symptom (pain), namely, pressure or inflammation. Then we are apt to look for too marked symptoms instead of giving attention to the lighter ones which are more frequently present. In one autopsy he had found a saccular aneurism large enough to contain eight ounces of blood which had started from the right side of the aorta, near the base of the heart; yet it had given rise to no symptoms from pressure on the recurrent laryngeal nerve or other structures. The patient did, however, have pain in the back during his last days, because of secondary inflammation. Another case which he had seen at Roosevelt Hospital was that of a man who, months before death, had profuse muco-purulent expectoration with no other physical signs than those of general bronchitis until three months before death, when evidences of small cavities in the upper part of the lungs developed. They were then able to detect the bacillus tuberculosis in the sputa. Death took place suddenly, when an aneurism, four inches in diameter, was found pressing upon the trachea just above its bifurcation. In addition thereto was a sacculated dilatation of one bronchus and a large number of fresh miliary tubercles. In the other case the patient complained of nothing but slight dyspnœa, preceded by temporary attacks of aphonia, which developed a few weeks before death. There were no physical signs. Death was sudden. A large aneurism was found to spring from the transverse portion of the arch, pressing upon the trachea.

Regarding the pathology, it had also seemed to him that endarteritis and endartheroma are not common causes of aneurism of the aorta. In Roosevelt Hospital he had found a large proportion of patients of middle life suffering from more or less advanced disease of the intima, yet, as Dr. Biggs had said, persons in whom there had been most disease of the intima had not been those affected by aneurism.

In his cases it had been rather the rule not to find blood in the lungs. Regarding causes of sudden death, aside from rupture of an aneurism, he thought it resulted not infrequently from heart-trouble, although no valvular cardiac disease was present.

Dr. W. H. Katzenbach could speak of aneurism only from a clinical stand-point. He knew of no disease which gave rise to more suffering in the way of dysphagia, dyspnœa, and vomiting than occurred in some cases of aortic aneurism. For some years he had entertained the view that syphilis is the chief cause of the degeneration of the arterial coats which leads to aneurism. Yet he had seen some cases of aortic aneurism which seemed undoubtedly due to gout or rheumatism. Dr. Katzenbach cited some cases, in one of which the man lived a week after rupture of the aneurism, the autopsy revealing an aneurism of the thoracic aorta which had ruptured into the lungs and left pleural cavity. With regard to symptoms, he said that when a patient over forty years of age came complaining of dysphagia, peculiar barking voice, perhaps crowing respiration, and expectoration of bloody mucus, he would suspect aneurism. It was the exception for a bruit to be heard in thoracic aneurism.

Dr. S. S. Burt's clinical experience supported the observations made in the paper. The aneurism usually occurs on the ascending aorta, and the patient fails to consult a physician because the pressure-symptoms, especially that of pain, are absent, or but slight in degree. He had noticed alteration of the voice oftener than difficulty in swallowing. It had been mostly by discovering dulness and pulsating tumor that he had been able to make the diagnosis.

Dr. William H. Thomson thought that aneurisms of the thoracic aorta are among the most difficult of all cases for clinical study. It would be hard to conceive how aneurism of the ascending portion of the arch can produce many symptoms, as long as it is intra-pericardial. The heart usually maintains its normal size, and in quite a number of cases it retains its normal position. By pressure upon the bronchus it may cause changes in the breathing, and now and then lobar pneumonia, but not as commonly as does aneurism of the transverse portion of the arch. But when the transverse portion is affected the symptoms are likely to be marked, on account of the involvement of so many important organs in that immediate neighborhood. These symptoms point strongly toward aneurism, and are likely to be confounded with those of but one other condition, namely, a tumor. In the case of a tumor the veins over the thorax, as far down as the diaphragm, are distended; in aneurism their dilatation is limited to the region of the sternal notch. He had yet to see a case in which there was implication of the recurrent laryngeal nerve and yet the breathing remain natural.

In aneurism of the descending portion of the arch there is frequently pain, and it is of a significant character, being limited to one or more intercostal nerves. It shoots from the back, and is not aggravated by the movements of respiration.

Dr. Thomson felt much like coinciding with the views of Dr. Biggs regarding the part taken by syphilis in the etiology, notably in aneurism of the aorta. The only remedy which he had found of any avail was iodide of potassium, administered in the manner indicated in constitutional syphilis.

There was one point in the etiology of aneurism which he did not yet fully understand, namely, the part taken by severe muscular exercise, which is so commonly present in the history of these cases. He had observed the affection oftener in iron moulders, and those who do heavy lifting and breathe intermittently than in any other class of workers. In holding their breath while lifting heavily they throw a great strain upon the mitral valve, it is true, but next, the strain falls upon the aorta.

The Chairman had always regarded thoracic aneurism as somewhat difficult of diagnosis. Some years ago a patient was shown at Bellevue Hospital as a typical case of pleurisy with effusion. Death resulted suddenly from rupture of an aortic aneurism. No pleuritic effusion was present. Regarding causes of sudden death in general, he thought heart disease, in which nothing but aortic regurgitation can be found during life, is a frequent cause. He, too, had found iodide of potassium the only remedy of benefit. Regarding syphilis as a cause of aneurism, he had not seen a case of aortic aneurism in a patient under thirty years of age who had not a syphilitic history.

Dr. Leonard Weber had in his early professional career seen three or four cases of aortic aneurism in which there was no other apparent cause than lead-poisoning. As to the influence of muscular exertion, he had seen about a dozen cases of aortic aneurism, and in none had there been a history of over-muscular exertion. Syphilis was present in most of them, but in one it was excluded. That patient was subject to chronic alcoholismus. There were also two cases of gout, in which syphilis could be excluded. Regarding iodide of potassium, when he wished to give it for a long period he administered it in small doses.

Dr. Birdsall said the changes produced by syphilis, in the small arteries at least, are a proliferation and occlusion. This was not the condition found by Dr. Biggs in aneurism of the aorta, which he believed usually to be due to syphilis.

Dr. Biggs could not say that the changes in the artery in aortic aneurism are not those of syphilis, yet they are not those alterations of syphilis found in other organs. He had arrived at the conclusion that aortic aneurisms are due to syphilis, more from exclusion than from anything else.

He had found in very few of the cases changes in the valves or muscle of the heart. That the cause of aneurism in the small arteries, especially those of the brain, is not the cause of aneurism in large arteries is evident from the fact that the affection seldom exists in the two localities in the same individual; aneurism of the aorta is usually unaccompanied by aneurism in the small arteries.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 25, 1888.

W. P. Northrup, M.D., President, in the Chair.

Dr. W. B. James presented a series of microscopical preparations of blood taken from patients suffering from malarial fever, which demonstrated the various forms of the

MICRO-ORGANISMS OF MALARIA (see p. 269).

Dr. Mendelson asked whether any relationship possibly existed between the Hæmatozoön malariæ and the Filaria sanguinis hominis, since they had some points in common, namely, that both were blood-parasites; both appeared intermittently, giving rise to paroxysmal seizures.

Dr. James did not know of any connection between the two. Zoölogically they were quite distinct—the filaria belonging to the nematodes, the hæmatozoön to the protozoa. The presence of filaria in the blood was interesting, however, in that it suggested the possibility of a parent-organism existing within the body, and there discharging its young. It has been surmised that in malaria the parent-organism resides in the spleen, and there discharges its young, this discharge being the exciting cause of the malarial paroxysm. In the blood taken from a patient after the chill we find spores and pigmented amœboid forms, but whether these are a brood which will later become mature we are as yet unable to say. Laveran regarded the flagella as the fully developed organisms.

Dr. Prudden wished to call attention to one point suggested by the paper. This was the change which is taking place in regard to the proof deemed necessary to establish an etiological relation between micro-organisms and disease. In the early period of modern bacteriological investigations—that is, those carried on by means of the methods devised by Koch—it was deemed necessary, in order to definitely establish an etiological relationship between a given species of bacteria and a disease in man, first, to show its constant occurrence in connection with the lesions of the disease; second, to completely isolate it by culture; third, to produce, by inoculation with the pure culture in some of the lower animals, lesions identical or closely analogous with those found in man; and, fourth, to demonstrate the presence of the micro-organism in the lesions. It is noteworthy that the first diseases completely investigated in the light of the new methods were those which are frequently found in both men and lower animals. But we have learned that there are other diseases, common in man, to which the lower animals are not only not naturally subject, but to which they are quite invulnerable by any of the experimental methods yet known to science. So that at present, while in every case positive results from inoculations of pure cultures are ardently sought after, we must always be prepared to find that one step in the chain of evidence must perforce be dispensed with. Unfortunate as this is, we should not forget that, with every acute infectious disease whose relationship to bacteria has been completely demonstrated, the morphological evidence alone becomes stronger in those other diseases which we cannot reproduce in animals.

Thus it was that the accumulation of morphological data such as Dr. James had laid before the Society in his paper assumed a significance greater than was evident before the limits of experimentation had become as well defined as they are to-day.

The President announced as the

COMMITTEE ON MICROSCOPY

for the ensuing year, Drs. J. S. Thacher, Ira Van Gieson, and H. M. Biggs.

The Society then went into executive session.

Stated Meeting, February 22, 1888.

W. P. Northrup, M.D., President, in the Chair.

The President presented, on behalf of a candidate, a *kidney of a dog containing a large calculus.*

Dr. Frank Ferguson presented, on behalf of a candidate, a specimen of *cancer of the pylorus with secondary neoplasms in other organs.*

Dr. Ferguson then presented a specimen of

GUMMATOUS TUMORS OF THE LIVER,

the larger ones being about three-fourths of an inch in diameter. The patient was a man, about twenty-nine years of age, who was admitted to the Chambers Street Hospital a few hours before death. He was in a comatose condition on admission, and no history of the case could be obtained.

A second specimen was one of

ENCHONDROMA OF THE STERNUM,

removed from the body of a man who had died of general peritonitis following perityphlitis. The tumor was composed of cartilage with strands of fibrous tissue running through it, and in places small fragments of bone were found. It measured 12 ctm. in length, 7 in width, and 4½ antero-posteriorly.

Dr. Mary A. Dixon Jones presented a specimen of a large

FIBROID TUMOR OF THE UTERUS,

removed by operation from a woman six days before. The patient was forty years of age, had been married twice, but never had had any children. Examination showed the presence of a large solid, fibroid tumor of the uterus, filling the whole abdomen as far as the ensiform cartilage. The growth had evidently existed for a very long time, but had troubled her more especially during the last five or six years. The abdomen was opened, the tumor freed partly from adhesions, and a portion cut away. Then the clamp was secured lower down and another portion was removed. The pedicle thus secured was seen to consist of a mass of tumors, so it was decided to perform vaginal hysterectomy to remove the rest of the tumor.

The entire tumor-mass weighed thirteen and one-half pounds. The upper third consisted of a single solid mass, the remainder being composed of a number of smaller tumors, varying from one and a half to four and a half inches in diameter. The left ovary was enlarged, containing a hæmatoma two inches in diameter. The tube measured five inches in length and was filled with pus, the fimbriated extremity being closed and adherent to the ovary. The right tube was enormously enlarged and was coiled upon itself. The end, which presented no trace of fimbriæ, was closed, the tube measuring here three and four-fifths inches in circumference, and being filled with a bloody fluid.

DR. D. BRYSON DELAVAN related a case of

EPITHELIOMA LARYNGIS.

"A. S. J——; United States; aged fifty-eight; married; merchant. Family history excellent. Ancestors remarkably healthy and long-lived. Was brought up on a farm. Has always enjoyed perfect health. No diathesis discoverable. Has never used tobacco or alcohol in any form. Has lived much in the open air. In the summer of 1885 he caught cold, which affected his larynx. The resulting hoarseness never entirely disappeared, but became worse by degrees until the winter of 1886, when he became aphonic. About this time marked irritation of the larynx set in, causing considerable annoyance. Dysphagia followed, and later, dyspnœa. The latter became so severe that in June, 1887, he applied for relief at the Throat Department of the New York Polyclinic, having been referred by Dr. M. Allen Starr. On examination, the patient appeared a large, splendidly developed, vigorous man. His heart, lungs, and abdominal viscera, so far as could be ascertained, were normal. He was aphonic and was suffering from urgent dyspnœa. Laryngoscopic examination revealed the following condition: The mucous membrane of the larynx was deeply congested; the left arytenoid prominence was tumefied, the swelling extending over the whole of that side of the larynx; the left false cord was greatly enlarged and projected so far beyond the median line as to cause almost entire occlusion of the glottic aperture; the left vocal band was partially destroyed by a deep ulcer, which had its origin, apparently, in the adjacent sacculus laryngis, and which extended throughout the middle third of the band and downward below the glottis. There was no cachexia apparent and no involvement of the neighboring cervical glands. The appearance of the ulcer, together with the history of the case, at once suggested malignant disease, and, by reason of the urgency of the dyspnœa, an immediate tracheotomy was advised. To this the patient objected. On his return home the dyspnœa increased and by the following afternoon became so severe that asphyxia was threatened, and I was hastily summoned. Tracheotomy was performed and a cannula was inserted, to the patient's immediate relief. Microscopical examination of fragments of the tumor proved it to be epitheliomatous. Following the introduction of the tube, as is common in such cases, the condition, both general and local, improved, and all of the laryngeal lesions ameliorated to a marked degree. About this time he was seen in consultation by Dr. William T. Bull, who advised laryngectomy. This he would not permit until, as he said, he had seen the result of a similar case upon which Dr. Bull had just operated. The danger of delay was urged, but his decision was unalterable. During July the improvement ceased, and in August the disease again began to make steady progress. When, in the latter part of August, having seen the brilliant result attained in the case above mentioned, he at last consented to an operation, it was found that the whole of the thyroid, the cricoid cartilages, and even the hyoid bone were involved, and the neighboring tissues were infiltrated, so that extirpation of the larynx was no longer justifiable.

"The progress of the disease was now rapid, the whole interior of the larynx becoming involved and the cartilages increasing in size until, finally, they attained about four times their usual dimensions. There were profuse and annoying expectoration, cachexia, considerable emaciation and insomnia, but little dysphagia and that easily relieved by the application of cocaine, a fair degree of general strength, and no glandular involvement.

"The patient's condition grew gradually worse until January 1, 1888, when he complained that the tube seemed to be obstructed, and that removal and cleansing of the inner cannula did not relieve it. Examination of the trachea with a soft, flexible probe revealed the presence of a mass of tissue, of soft, friable consistence, upon the left side of the trachea and extending downward below the end of the tube. The removal of the most prominent part of this obstruction gave relief to the dyspnœa for several days; the attendant was instructed to remove the tracheal tube and insert far down the trachea a large soft catheter whenever an attack of dyspnœa occurred. This succeeded in temporarily relieving the tracheal stenosis, but the attacks of dyspnœa came on with increasing frequency, and during one of unusual severity the patient died.

"The principal points of interest, pathologically, in the above were, first, the extension of the growth into the trachea to so great a distance; and second, the fact that the adjacent glandular structures remained uninvolved."

DR. J. WEST ROOSEVELT presented (see p. 233)

A SERIES OF HEART LESIONS.

DR. FRANK FERGUSON presented a specimen of

TUBERCULAR PERICARDITIS,

showing marked thickening of both layers of the pericardium. The patient was a boy, ten years of age, born in Italy. For a year he had been in the habit of drinking from three to seven glasses of beer a day, and had smoked cigarettes excessively. One year ago he had a violent cough, accompanied by fever, which lasted for ten days, during which time he was delirious. There was no expectoration, but the boy had pain in the right side of the chest and was unable to lie on that side. There was no dyspnœa. This attack lasted for two months, and left the patient weakened and drawn over to the left side. Two months ago he had a similar attack, and for a year he had had some fever and a cough in the morning. One week before admission to the hospital, on November 5, 1887, he began to have increased cough and fever. There was no chill. The patient had dyspnœa and pain in the right side on coughing. The fever lasted but one night. and there was no expectoration nor spitting of blood.

Physical examination.—The right side of the chest was markedly retracted, and expanded scarcely at all during respiration. There was dulness anteriorly at the apex. Vocal fremitus was exaggerated, and there were many fine moist râles. On the right side, posteriorly, below there was dulness—lost vocal fremitus, and diminished breathing. The cardiac action was rapid—no murmur. The abdomen was distended, and the abdominal veins were markedly enlarged. There was a well-marked sensation of fluctuation. The liver extended from the fifth rib to a full hand's breadth below the free border, and it was somewhat tender.

Both chests were tapped and clear serum was withdrawn from the left. Urine yellow, acid, 1.006; no albumin. The patient became progressively worse, complaining of pain, sleeplessness, and dyspnœa, and getting weaker daily. He died on November 27th.

Autopsy.—Four hours after death. The peritoneum contained 1,500 c.c. of straw-colored serum. The diaphragm was on a level with the fifth interspace on each side.

There were firm old adhesions everywhere on the right side, and the pleura was much thickened. The pleural cavity contained lymph. On the left side were found old adhesions at the apex and 1,000 c.c. of clear serum. The upper lobe of the left lung was in the condition of gray hepatization. The lower lobe was œdematous. The right lung was firmly compressed and contained no air.

There were recent adhesions everywhere between the two layers of the pericardium. The heart was drawn toward the right. Its cavities were moderately dilated, but the valves were competent and the endocardium was normal.

Dr. H. M. Biggs presented a specimen of

ULCERATIVE ENDOCARDITIS.

The patient had been an attendant at the Charity Hospital for a number of years. He had never complained of any heart-trouble, and was sick only about eighteen hours before his death. On post-mortem examination both lower extremities were seen to be covered with a large number of petechiæ. The heart was hypertrophied and dilated, following an old pericarditis with obliteration of the pericardial sac. The mitral valve was the seat of an old trouble, as shown by the presence of some calcareous nodules, and also presented the lesions of recent endocarditis. The case was interesting on account of the sudden onset and short duration of the symptoms, and also because the changes in the heart were not of such a nature as to furnish the source for the numerous emboli necessary to account for the large number of petechiæ on the lower extremities. There had been a number of cases of small-pox in the hospital, and the man had had charge of the clothes of these patients. It was possible, therefore, that the case was one of hemorrhagic small-pox.

A second specimen was one of

RUPTURE OF THE HEART,

occurring in a man, fifty-eight years of age, a stone-cutter by occupation. He was apparently perfectly well, with the exception of some dyspnœa, on retiring one night, and was found dead in bed the following morning. At the autopsy the pericardium was found filled with blood, which had escaped through a small rupture in the antero-lateral wall of the left ventricle. There was no thinning and little, if any, dilatation of the heart. There was a clot along a branch of the coronary artery, but the vessel was almost perfectly normal, and was not ruptured.

Dr. Biggs also presented a third heart, removed from a patient in whom there had been heard, before death, a

MUSICAL SYSTOLIC APEX-MURMUR.

Death occurred from pulmonary trouble, and at the autopsy no cause was found to account for the murmur except a small chorda tendinea running through the ventricle.

The fourth and fifth specimens showed

MULTIPLE SECONDARY GROWTHS.

In the first case the growths were in the myocardium of the right auricle and ventricle, and followed primary carcinoma of the kidney. The lesion had not manifested itself by any physical signs before death.

In the second specimen there were similar growths, mostly in the walls of the left ventricle. The primary cancer was in the left ovary, and was of small size. The patient had died suddenly in an attack of cardiac syncope, there having been no symptoms suggestive of a serious affection previously, with the exception of one or two not very severe attacks of syncope.

The last specimen was one illustrating

ULCERATIVE ENDOCARDITIS,

occurring in a case of pyæmia. Pure cultures of the staphylococcus pyogenes aureus were obtained from the vegetations on the valves, and from necrotic patches in the kidneys.

Dr. G. L. Peabody presented specimens showing a

TRAUMATIC ANEURISM OF THE LEG,

following the lodgement of an embolus, and valvular heart-lesions. The patient was a man, twenty-two years of age, born in England, a nurse by occupation. He gave no history of any heart-trouble or of any disease ordinarily causing cardiac lesions. He was, according to his own report, perfectly well up to one week before admission to the New York Hospital. At this time he began to be troubled with dyspnœa, and soon after felt a sudden sharp pain in the calf of his right leg. Upon admission an examination showed an increased area of precordial dulness, and there was a distinct mitral systolic murmur and also a double aortic murmur. The pain in the calf steadily increased, and a pulsating tumor appeared in this situation. The patient died from exhaustion without presenting any further symptoms of interest.

Autopsy.—Two hours after death. The right leg and foot were found to be greatly swollen and œdematous.

The pericardium was normal. The heart was large, there was great hypertrophy of the left ventricle, and the muscular tissue was pale and flabby. The valves of the right side were normal. On the ventricular surface of one aortic cusp was a recent vegetation with a base of attachment measuring one-half by one-fourth of an inch. The ventricular surface of the mitral valve was roughened and covered by recent fibrinous masses, which were firmly adherent to the surface of the valve. The surface beneath them was roughened. The free edges of the segments of the mitral valve were ulcerated. Several of the tendinous cords were seen to be completely separated from the cusps. The lungs showed hypostatic pneumonia, besides the interstitial process common in mitral disease.

The spleen was somewhat larger than normal, and contained several old decolorized infarctions.

The only other parts of the body that presented lesions of interest were the tissues of the right leg. In this the femoral and popliteal arteries were normal. A rent was discovered in the posterior tibial artery, near its origin, which established a communication with a large, irregular, ill-defined cavity filled with recently coagulated blood. The inner surface of the walls of this traumatic aneurism was seen to be smooth in some places; in others, it was made up of lacerated muscular tissue. The intermuscular spaces of the calf of the leg were filled with blood, as was also, in some places, the subcutaneous tissue.

The length of the aneurismal sac was twenty centimetres, and its diameter half as great.

Dr. Peabody regarded the case as one of interest from its unusual features, especially the development of the traumatic aneurism following the lodgement of an embolus in the posterior tibial artery, together with the absence of all previous history of heart disease, or of any of the usual causes of heart disease.

Dr. F. T. Hopkins presented a specimen of

INCOMPLETE CLOSURE OF THE FORAMEN OVALE; PATENT DUCTUS ARTERIOSUS.

The patient, Louise F——, came under his care at the New York Foundling Asylum on February 3, 1888, when she was two weeks old. She was suffering from diarrhœa, which had begun two or three days before. She was a small, miserable-looking baby, weighing about five pounds. At this time she was decidedly cyanotic, and the mother stated that she had been a "blue baby" from birth. No signs of pulmonary trouble, and no abnormal cardiac sounds could be detected. There was a slight improvement noticed in the cyanosis upon the cure of the enteritis, but it was only temporary. The cyanosis again deepened, and the child became somewhat stupid, and died on February 9th.

The autopsy was made two days after death by Dr. Northrup. The lungs were fully developed. There was no inflammation, but a moderate hypostasis of both lungs. The heart weighed six drachms. The foramen ovale was in part closed by a semilunar membrane, imperfect in its upper anterior portion, where it was thick and redundant, and retained its fœtal, valvular character. In addition to this, there were two openings in the lower posterior portion of the septum, which had no valvular character, and could not prevent the passage of blood through them. These last two openings were respectively about one and two millimetres in diameter, and allowed the venous blood to pass directly into the left auricle. The ductus arteriosus was pervious, and an ordinary grooved director could easily be passed through it. The heart and great vessels were otherwise normal. The liver was fatty, and weighed four ounces. The spleen weighed half an ounce. The other organs were normal.

THE PRESIDENT presented a specimen of

REPTILIAN HEART (see p. 353).

The President then presented a second specimen, showing

ANEURISM OF THE INTERAURICULAR SEPTUM WITH PERVIOUS FORAMEN OVALE.

The patient was a male child, one week old. He was brought to the New York Foundling Asylum, three days before death, with a history of having been moderately "blue" from birth, and of frequently crying very hard, at which times he became "black in the face." During the remaining days of life he became more and more cyanotic; the temperature of the body fell below normal; the pulse gradually failed; the breathing ceased. At death the contrast of the child's purple skin against the white bed was strongly marked.

At the autopsy the lividity was seen to be most pronounced about the head and upper portion of the trunk and arms. The body was well developed; the umbilical cord undetached. The lungs were fully inflated and normal.

The heart was large, the left ventricle distended, its walls thin. The foramen ovale was pervious, and large enough to allow an ordinary lead-pencil to pass through. This opening was at the anterior upper margin of the fœtal foramen, the remaining portion being filled by a crescentic membrane advancing from attachments upon the entire remaining periphery. This membrane, instead of being tense and tending to contract the orifice, was lax, and, together with the adjacent portion of the auricular septum, became prolonged into an aneurismal sac. The finger-tip, pushed gently against the lax membrane, carried it forward half an inch, the first phalanx being covered as with a glove-finger.

The specimen showed the aneurismal sac, which had been distended; also the aperture, which was as large as the average fœtal foramen, though apparently partially closed by the valve-like margin of the crescentic membrane.

The other organs were normal. The condition of the foramen ovale was believed to be the cause of the cyanosis. The ductus arteriosus was contracted, and allowed little or no blood to pass.

The Society then went into executive session.

THE DRUG-STORES IN GERMANY AND THE UNITED STATES.—The drug-stores have a curious way here of shutting up just about the time you want them. And as soon as it begins to grow dark, down go the shutters, and if you need anything you go to a little bell-handle outside of one of the iron shutters and ring it. Then you hear someone at a crank inside, the massive frame rolls up, and a head looks out the window. Finally the man or boy inside opens part of the window and you talk through a pane of glass and make known your wants. Instead of angry at being aroused, the man begs your pardon for keeping you outside and says: "I thank you for your order." If you have not the exact change, and the man inside is in the same predicament, he will beg you most politely and thank you to allow him to change it. Having done so he will thank you for calling (evidently taking the visit as a social one), bow, close his little peep-hole, bow again, and then smile sweetly as he grinds down his iron shutter, and his smiling face is lost to view. How different from the druggists in America! I remember I once woke one up in the States and he came down-stairs with a shotgun after me. But, as I remarked before, they have a curious way of doing things in Dresden.—*Dresden Correspondence.*

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PRESIDENTIAL ELECTION AT THE COLLEGE OF PHYSICIANS—THE BRITISH MEDICAL ASSOCIATION AND RELATIVE RANK—SUCCESSFUL TREPHINING FOR CEREBRAL ABSCESS—THE ASSOCIATIONS OF GASTRIC ULCER—THE PROGNOSTIC SIGNIFICANCE OF LOW ARTERIAL TENSION IN KIDNEY DISEASE—THE PATHOLOGICAL SOCIETY—SOME RECENT DEATHS.

LONDON, March 13, 1888.

THE topic of the day is the coming election at the College of Physicians. Having served seven years, it is understood that Sir William Jenner will not consent to be re-elected; a fresh president has, therefore, to be chosen. A year ago it might fairly have been said that the running lay between Sir William Gull and Sir Andrew Clark, and though the former has made many enemies, he would, I think, have gained more votes than Sir Andrew Clark had there been a real contest last year for the Presidency. Sir William Gull's state of health, however, precludes him from being now nominated. Among others, Sir Andrew Clark, Sir Edward Sieveking, Dr. Quain, and Sir Henry Pitman may be regarded as likely candidates. Sir Henry Pitman has been Registrar of the College since 1858, and was an unsuccessful candidate for the Presidential chair in 1876, on which occasion the choice of the Fellows fell on Sir Risdon Bennett. Sir Henry Pitman is considerably advanced in years, but it is suggested that his intimate acquaintance with college routine would prove very valuable at the present juncture, and he is known to be in accord with Sir William Jenner in most matters of collegiate policy.

The British Medical Association received a somewhat decided snub in the House of Commons yesterday evening. Dr. Farquharson asked the Secretary of State for War whether he had received from the Association a statement containing an analysis of the opinions of nearly twelve hundred army medical officers with reference to the abolition of relative rank, and also whether a widespread feeling of dissatisfaction had not been shown to exist throughout the department. Mr. Stanhope replied that he had received the communication, but that the opinions contained in it appeared to have been obtained in a manner altogether in contravention of military rules. Medical officers, like others, had a proper channel through which to be heard, and he was not prepared to accept a civilian circular from any association on their behalf. Mr. Stanhope, whose remarks were greeted with cries of "hear, hear," further proceeded to state that the status of medical officers was precisely what it was before the recent changes.

At last week's meeting of the Medical Society of London Dr. Ferrier and Mr. Victor Horsley contributed a joint paper of considerable interest. In it was narrated the case of an artisan in whom acute otitis media was succeeded in a few weeks by cerebral abscess. The abscess was tapped and six drachms of pus withdrawn. Antiseptic precautions were employed, and the wound united by first intention. It had completely healed by the twenty-fourth day after the operation. The case was a remarkable one of recovery from a grave condition, as before the operation there was intense optic neuritis in both discs, with hemorrhage into the right. There was also almost complete motor aphasia, paresis of right side of face, and (less marked) paresis of the right upper limb. The abscess was situated one centimetre from the surface. An inch disc of bone was removed after incising the soft parts. On removal of the bone the dura mater was found congested and bulging. On opening it œdematous brain bulged out. This was tapped with a trocar and cannula, and creamy pus withdrawn.

Dr. Ord read a paper on gastric ulcer, and narrated some curious coincident conditions which he had observed. In an anæmic woman under his care, suffering from gastric ulcer, some heart symptoms (from which she was suffering) underwent further development. He had previously noted the coexistence of symptoms of gastric ulcer with those of pericarditis and endocarditis, in three cases. In a case at present under his care, signs of gastric ulcer, cardiac inflammation, and optic neuritis were all present, in conjunction with extreme anæmia. He was inclined to regard the curious combinations of lesions noticed as consequent on anæmia. A short discussion ensued, in the course of which Dr. Maclagan mentioned a case in which a lady aged fifty, after sudden, profuse gastric hemorrhage, developed an endocardial murmur with a slight rise of temperature. In another case, a neurotic patient, subject to gastric irritation, developed an apex systolic bruit.

Dr. Broadbent then read a paper on the prognostic significance of blood-pressure in acute renal disease. In almost every form of kidney disease, he said, arterial tension was high, but he had twice seen low tension when symptoms of renal cirrhosis were present. In acute renal dropsy, when the pulse-beats were short and easily arrested, it indicated temporary dilatation and weakness of the left ventricle. Continued low tension might be due to persistent cardiac weakness, and the prognosis of this was unfavorable. It might also be due to diminished peripheral resistance, which was also unfavorable. Low blood-pressure indicated a long illness and the necessity for using vascular stimulants.

Dr. Maguire remarked that he had found cases of high tension best relieved by calomel and salines. Where tension was low, nux vomica and iron were indicated.

At the last meeting of the Pathological Society several specimens of interest were shown, and also some living patients. Mr. Shattock exhibited a specimen of epithelioma of the kidney associated with calculus. The growth was not of the glandular type usual in malignant renal tumors, but was a true epithelioma, and probably due, he thought, to the irritation of the calculus. Mr. Walsham observed that such cases afforded a powerful argument for early interference in cases of suspected calculus. Mr. Bernard Pitts showed a specimen of villous carcinoma removed from the breast of a lady fifty-three years of age. Dr. Norman Moore showed two specimens of renal disease. Mr. Hurry Fenwick brought forward statistics of sixty cases of villous papilloma of the bladder from different sources, showing the varying conditions which might be encountered by surgeons in dealing with these growths. In regard to carcinomata, he had found that they might exist in the same bladder with benign growths in the proportion of ten per cent., and observed that this would be an important factor in the surgical treatment of such cases. He also showed some specimens to prove that carcinoma might propagate itself by contact. Several of these specimens showed growths on both sides of the bladder where the walls would obviously be in contact when the bladder was empty.

The oldest Fellow, but one, of the College of Physicians —Dr. John Burdett Steward—died a week ago, at the age of ninety-four. He took the degree of M.D. at the University of Cambridge in 1829, having become a member of the College of Physicians a year previously.

Mr. Thomas Blizzard Curling, F.R.S., formerly President of the College of Surgeons, died at Cannes a few days ago at the age of seventy-six.

THAT "ORAL WHIFF."

To the Editor of The Medical Record.

Sir: The Medical Record of March 3, 1888, on page 235, contains an article entitled "The Oral Whiff," by Dr. W. S. Cheesman, of Auburn, N. Y., which interested me particularly because I have noticed the same phenomenon in myself, and because the manifestation seems to be looked upon as something somewhat unusual.

The origin of the phenomenon in question can be easily accounted for if we cease to look for a pathological explanation.

Now, what were the physiological conditions in the few cases given in detail by Dr. Cheesman? The heart was in unusual activity, in one case from active exercise, in the other from mental excitement—after running, during a political wrangle, etc. It is stated in Case I. that the whiff ceased when the heart's action became composed, only to reappear upon renewal of the exertion. In a case which came under my own observation the patient noticed the "oral whiff" only after the completion of the sexual act, while both respiration and the heart's action were accelerated, passing off as the heart ceased its tumultuous action.

Of course, auscultation at this time will reveal the puff at each systole, and, as the excited action lessens, the puff gradually becomes weaker, until nothing is heard but a slight emphasis of the natural vesicular breathing at each systole, which may also be heard in most persons irrespective of unusual activity of the heart.

Looking at the phenomenon from a physiological side, we would not expect any pathological manifestations, such as dyspnœa, abnormal heart-sounds, etc.

Gerhardt[1] considers it to be physiological, and even claims that from its absence it might be possible to diagnosticate adhesions of the pulmonary borders proximal to the heart.

Wintrich[2] speaks of the phenomenon as occurring quite often, and calls it "systolic vesicular breathing." He explains it in the following way: The lungs are constantly endeavoring to adapt themselves to changes in the volume of the chest, not only such as are manifest externally, but also those occurring within the chest, such as the contraction of the heart. The heart becomes smaller, and the contiguous portions of the lungs become overfilled with air, striving to fill out the extra space as it were. This rush of air is heard as systolic vesicular breathing. He goes on to say that the presence of this phenomenon seems to be the rule, but its absence is often noted.

Guttmann[3] says it is caused by the sudden rush of air into the alveoli of those parts of the lung contiguous to the heart, which rapidly expand and occupy the space rendered vacant by the shrinking of the heart in systole.

Julius Otto, M.D.

125 State Street, Chicago, Ill.

SHALL SURGICAL INVENTIONS BE PATENTED?

To the Editor of The Medical Record.

Sir: In your issue of March 17, 1888, there appears an article by Dr. Incognito entitled, "Shall a Surgical Invention be Patented?" and upon the same he invites discussion by the readers of The Medical Record—if unbiassed. Now since I do not know Dr. Incognito, and am not an inventor, this may be considered as unbiassed.

The doctor at once disclaims the propriety of defending secret medicines, yet compares his (an) invention to them. Now, Mr. Editor, space to you is valuable, and as one's mind can as well be understood in a few words as many, let me ask, briefly, What is a surgical invention the result of, and what is it for? We understand it to be the result of the doctor's patient study of the disease in hand, and the outcome of his professional education. It is intended for the relief of suffering humanity and to assist him in complying with the promise he made when graduated a doctor of medicine to do all in his power for the relief and cure of those under his care. If the doctor does not approve of the proprietary medicine, he certainly would disapprove the conduct of a brother physician, who, discovering a specific for a certain disease, withheld it from the profession (thus making himself proprietor), that all suffering from the disease should be compelled to consult him, thereby elevating his professional standing among men and increasing his income. Yet where is the difference? If the invention is of value, the instrument-maker gladly takes it at a specified royalty, or the doctor manufactures it himself, and puts the profits into his pocket. In either case it is saying plainly to the profession: You can have it, but must pay me for it. Your sick ones can have it, but they are indebted to me to such or such an amount for the good it may do them.

---

[2] Gerhardt: Lehrbuch d. Auscultation u Percussion, 1876, p. 181.

[3] Handbook of Physical Diagnosis, 1877, p. 98.

To my mind it is unprofessional, and a physician or surgeon should be above it. They should not consider their inventions or discoveries as commodities, to be sold or exchanged as luxuries, and the profits resulting for their personal benefit. As he would not withhold a remedy known to cure a certain ill, so should he give to the profession and people the result of his inventive mind. If for no other reason, this one is sufficient, that he alone was permitted to give to medicine or surgery something to mitigate the suffering he daily witnessed, mindful of the fact that if good came of it his name would be connected with it, and, if not pecuniarily benefited, he would have the grateful remembrances of the user and the respect of his professional brethren.

HOWELL WHITE, M.D.

FISHKILL, N. Y., March 19, 1888.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: After reading "Dr. Incognito's" letter in your last issue, I am prompted to ask a question which has occurred to me before.

What difference is there between a physician's holding a patent on an instrument and holding a copyright on a book? Are not both virtually patents? A copyright gives the author exclusive control over the publication of his book, and gives him a royalty on each copy published. A patent gives the patentee exclusive control over the manufacture of his invention.

Where is the difference?

A book is the result of a man's brains; so is an instrument. Both are a benefit to the profession. Both cost money to elaborate, and time and labor to perfect.

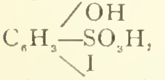
But do we give the book to the publisher and let him reap the profits? I pick up from my desk a book on "The Eye," by a noted specialist, and on a front page find "Copyrighted by so and so," and in italics "*All rights reserved.*" In other words, it is patented. But if it is an instrument that has cost years to perfect, we must not patent it; it would be unprofessional. "Oh, consistency, thou art a jewel!"

In closing, I will say that I am not an inventor, nor have I any axe to grind; but what is sauce for the goose, ought to be sauce for the gander.

E. C. ATKINS, M.D.

MILFORD, MASS.

SOZOIODOL, THE NEW DERMATOLOGICAL REMEDY.—This agent, introduced by Trommersdorff, appears in pure white crystals. It combines three of the best parasiticides known, being composed of iodine, carbolic acid, and sulphur. It is expressed chemically by the formula



$C_6H_3(OH)(I)—SO_3H$, or $C_6H_3ISO_3H$ (OH). Its usefulness is enhanced by its ready solubility in water and alcohol, and its chemical stability when mixed with various vehicles. Sozoiodol is free from odor, and is well borne by the sound and the diseased skin. It appears to have decided curative properties in eczemata of all descriptions, in herpes squamosus and tonsurans, impetigo, and ulcers. It is applied in the form of a powder or a lanolin paste. In barber's itch a ten per cent. paste has been found particularly useful. Its chief activity appears to be in parasitic affections of the skin.—*Therapeutische Monatsschefte.*

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 18 to March 24, 1888.

BAXTER, J. H., Colonel and Chief Medical Purveyor. Will proceed to Augusta Arsenal, Ga., on public business. S. O. 62, A. G. O., March 16, 1888.

SPENCER, WILLIAM C., Major and Surgeon. Died March 22, 1888, at Fort Trumbull, Conn.

GREENLEAF, CHARLES R., Major and Surgeon. Will proceed to Cambridge, Mass., on official business. S. O. 62, A. G. O., March 16, 1888.

FORWOOD, W. H., Major and Surgeon. Granted one month's leave. S. O. 20, Department of Dakota, March 10, 1888.

BROWN, H. E., Major and Surgeon. Assigned to temporary duty at Fort Barrancas, Fla., during the absence on leave of Assistant Surgeon M. C. Wyeth. On the return to duty of Captain Wyeth, Major Brown will rejoin his proper station. S. O. 65, A. G. O., March 20, 1888.

O'REILLY, R. M., Major and Surgeon. Will proceed to York, Pa., and make an examination of Captain Edward B. Rhum, Twenty-first Infantry. S. O. 62, A. G. O., March 16, 1888.

WORTHINGTON, J. C., Captain and Assistant Surgeon. Granted leave of absence for four months, to take effect May 15th, or as soon thereafter as his services can be spared. S. O. 65, A. G. O., March 20, 1888.

WYETH, M. C., Captain and Assistant Surgeon. Granted leave of absence for two months, to take effect about April 1st. S. O. 65, A. G. O., March 20, 1888.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 24, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	11	1
Scarlet fever	147	24
Cerebro-spinal meningitis	2	2
Measles	64	3
Diphtheria	134	57
Small-pox	23	3
Yellow fever	0	0
Cholera	0	0

IS LEUCOCYTHÆMIA CANCER OF THE BLOOD?—The question proposes an ingenious hypothesis supported by the histological contention that the blood, though fluid, is as much a tissue as the most solid of them all. M. Bard has written an article on the subject in the *Lyon Médical*, No. 7, in which he takes up the line that the disease is a new-growth, and remarks that if this process does not give birth to a tumor in the original sense of the word, it is because the neoplastic tissue obeys a pathological law and preserves the evolutionary attributes essential to its tissue of origin—the blood.—*The Lancet.*

THE ASSOCIATION OF SUPERINTENDENTS of Hospitals for the Insane has for years admitted homœopathists to membership, yet sends delegates to the American Medical Association. The College of Physicians and Surgeons of Chicago numbers an eclectic among its professors.—*Medical Standard.*

THE CARTWRIGHT LECTURES ON THE GENERAL PATHOLOGY OF FEVER.[1]

BY WILLIAM H. WELCH, M.D.,

PROFESSOR OF PATHOLOGY IN JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE I

THERE is no subject in medicine of more general and varied interest than fever. The practitioner in every department of medicine, the pathologist, and the physiologist are equally interested in the investigation of the nature and effects of fever. Even the physicist and the chemist, who are not directly concerned with medical science, have lent their aid to the study of animal heat and its disorders. The history of opinion regarding fever is in great part the history of medicine itself, for no feature of the great systems of medicine, from Hippocrates and Galen to the present century, so characterizes these systems as the views held concerning the nature of fever. In consequence of the importance of the subject and of the number and ability of those engaged in its investigation, it might be supposed that no chapter in medical science would be better understood than that pertaining to fever. That such is not the case is due to the fact, which is becoming more and more evident, that the reaction of the animal system which we call fever is dependent upon the most fundamental and essential properties of protoplasm and of nerve-energy. In proportion as our knowledge of these properties increases and becomes more accurate, we gain a clearer insight into the complicated processes involved in the production of fever.

I should hardly have selected for this course of lectures a subject where so many problems remain unsolved, and which must necessarily be presented in so fragmentary a form, were it not that in all ages the opinions held concerning the nature of fever have controlled measures employed in its treatment. In proof of this one need not go back to the time when fever was regarded as an almost conscious struggle of an anima with a noxious principle, in which struggle the physician was to interfere as little as possible; or to the time when fever was supposed to result from morbid humors, which the physician should aim to eliminate by the production of a critical discharge; or to the period when the treatment hinged upon the belief either in the sthenic or the asthenic nature of fever. In our own time the treatment of fever is intimately connected with the answers variously given to such questions as, whether fever aids in the elimination or destruction of infectious agents concerned in its production; whether increased waste of tissue is a constant condition and a source of danger in fever; what part is played by infection, and what part by elevation of temperature, in causing the grave symptoms of fever; what, in addition to lowering of temperature, are the effects of so-called antipyretic measures of treatment.

I need hardly say that the subject of these lectures relates to fever as a condition common to all febrile diseases. Some writers understand by the term fever, used in this sense, merely abnormal elevation of temperature; others, elevation of temperature and the symptoms directly caused by this; and still others, a complex of symptoms of which increased temperature is the most prominent symptom, but not necessarily the cause of the others. In considering the general pathology of fever it is convenient to adopt the last meaning, although it would doubtless be less confusing if the word fever were applied only to abnormal elevation of temperature.

Increased temperature being the dominant and essential symptom of fever, all discussions as to the nature of fever centre around the question, How is febrile rise of temperature produced? It is to the consideration of this question that I first invite your attention. As there are other aspects of fever which I wish to discuss, it will be necessary to present the matter belonging to this division of the subject in as succinct a form as is compatible with clearness. Twelve years ago Burdon-Sanderson brought together, in an admirable critical review, the results of investigations upon this subject up to that period. Since that time important additions have been made to our knowledge of the mode of production of fever.

In the wonderful preservation of a nearly constant temperature which characterizes in health the warm-blooded animals, three factors are concerned, viz.: The production of heat within the body, the loss of heat from the body, and the regulating mechanism by which the varying heat-production and heat-loss are so balanced that the internal temperature remains practically constant. It is theoretically possible that the rise of temperature in fever may be due to the disturbance of any one or more of these factors. It becomes necessary, therefore, to consider the behavior of heat-production, of heat-loss, and of the regulating mechanism in fever.

We will begin with a consideration of the production of heat in fever. The amount of heat produced by the body is estimated by two methods, one known as direct calorimetry, the other as indirect calorimetry. In the method of direct calorimetry the animal is placed in a closed ventilated box, surrounded on all sides by a compartment containing water or air, and the amount of heat discharged from the body is determined by the quantity of heat imparted to the surrounding water or air. If the temperature of the animal remain unchanged during the period of observation, the heat-production is equal to the heat-loss; if the temperature rise or fall, the amount of heat corresponding to this change of temperature—an amount determined by multiplying the weight of the animal by its specific heat and by the number of degrees of altered temperature—is added to or subtracted from the quantity of heat imparted to the calorimeter. Time will not permit me to enter into experimental details in this connection; it must suffice to say that the method of direct calorimetry necessitates the introduction of a number of corrections which cannot be determined with absolute accuracy, so that the results obtained are of relative rather than of absolute value.

Hitherto the estimation of heat-production in fever, by determining the entire amount of heat liberated from the body, has been made only upon animals in which fever has been artificially produced. The most elaborate researches of this nature are those of Senator and of Wood.[1] The experiments of Wood are of the greater value, because he extended his observations over longer periods of time.

---

[1] Delivered before the Alumni Association of Physicians and Surgeons, March 29, 1888.

[1] Senator: Untersuch. üb. d. Fieberhaften Process. Berlin, 1873. Wood: Fever; a Study in Morbid and Normal Physiology. Philadelphia, 1880.

In four of the seven calorimetrical experiments of Wood, on different fevered dogs, comparison can be made of the amount of heat produced hourly in fever with that produced by the same animal when fed, and when in a state of hunger. During the period of fever the animal was also in a condition of hunger. I have computed from Wood's tables that the average hourly heat-production during seven days, described as first and second fever days, is a little over twenty-three per cent. greater than that produced by the healthy animal during a state of hunger, the minimum excess being one per cent., and the maximum 55.5 per cent. If a comparison be made of different periods during the existence of fever, there are found to be even greater fluctuations in the amount of heat-production than these figures would indicate; this amount being sometimes more than double that in hunger, and sometimes considerably less than the average production in hunger. Moreover, these experiments show no definite relation between the height of the temperature and the amount of heat produced, nor is it possible to deduce from them any relation between heat-production and the different stages of fever, such as the more recent calorimetrical experiments of Wood, Reichert, and Hare appear to show, and which will be described later. An important outcome of these, as well as of all similar calorimetrical experiments, is that although the heat-production of an animal in fever is greater than that of one under like conditions of nourishment, it is, as a rule, less than that of the same animal upon a full diet.

There are many reasons which make it important to control the experimental results obtained from animals in fever by corresponding observations of human beings. The agents used in producing experimental fever have been generally putrid fluids or pus, the injection of which causes, sometimes, diminution instead of elevation of temperature. When fever is thus produced it is usually of short duration and of only moderate intensity, the rise of temperature being rarely more than four degrees and sometimes not more than one degree, Fahrenheit. Moreover, a large part of the important rôle played by the skin in the regulation of the bodily temperature in man is assumed by the lungs in these animals.

Complete calorimetrical observations of human beings in fever encounter difficulties which have not yet been overcome. The imperfect or incomplete methods employed by Liebermeister and by Leyden [1] in determining the heat-production of human beings in fever justify the inference that this production is increased, and apparently, as a rule, to a greater extent than in animals, but they do not warrant positive conclusions as to the quantity of heat produced.

We turn now to the results regarding febrile production of heat obtained by what has sometimes been called indirect calorimetry. Inasmuch as the heat-energy of the body is the result of chemical changes of its proteids, fats, and carbohydrates, it is evident that if we know the kind and the amount and the heat-value of the substances consumed in a given time within the body, we can compute their heat-production. These chemical changes, so far as their final products are concerned, are processes of oxidation. The heat-values of the substances consumed in the body were determined first by Frankland, and more recently, with greater accuracy, by Von Rechenberg, Danilewsky, and Rubner. The investigations of Pettenkofer and Voit have shown that in hunger almost exclusively fats and proteids are oxidized, and that in this condition, by determining the amount of oxygen absorbed and of nitrogen and of carbon excreted, we can estimate the quantity of fat and of proteid substance oxidized during the period of observation.

Physicians of past centuries regarded increased consumption of the material of the body in fever as so evident that it needed no especial demonstration, and after Lavoisier made apparent the sources of animal-heat it was accepted almost unquestioningly, until the last quarter of a century, that fever is essentially a process of increased combustion or oxidation. The immense historical importance of the promulgation, in 1863, of Traube's theory, which denied the dependence of fever upon increased production of heat, is that this theory has led to a careful inquiry into the grounds of beliefs hitherto generally accepted, and to the demonstration of the unsatisfactory nature of the evidence hitherto thought to be conclusive.

The striking loss of weight of most fever-patients is, as is well known, a fact of great clinical importance. Weber and Finkler have demonstrated that animals in fever lose weight more rapidly than healthy animals in hunger, and although observations on human beings with reference to this point are not concordant in their results, there can be little doubt that the tendency of fever is to cause a greater loss of weight than can be explained simply by insufficient nutriment. This tendency, however, may be masked by the retention of water within the body, as the investigations of Leyden and others have shown. While, therefore, the studies of the loss of weight in fever leave no doubt that there is increased destruction of tissue in this condition, we cannot consider this loss as an accurate measure of the increased destruction, nor, without further knowledge, as an indication of increased oxidation, still less as proof of excessive production of heat.

It was for a long time believed that the excessive excretion of urea in fever afforded satisfactory evidence of increased oxidation and of greater production of heat. We now know, especially from the researches of A. Fraenkel, that this is so far from being true that we can explain the excessive elimination of urea better upon the assumption of diminished than of increased oxidation of tissue. In certain pathological conditions, notably phosphorus-poisoning, the amount of urea excreted may be increased more than threefold notwithstanding, or, as Fraenkel believes, in consequence of diminished absorption of oxygen and elimination of carbonic acid. It can, moreover, be computed that even without any diminution of the respiratory gases the discharge of urea may be increased without greater production of heat. While, therefore, the enormous increase in the discharge of urea in fever sheds valuable light upon a most obscure subject, the nature of febrile metabolism, it does not, regarded by itself, afford us any information as to the production of heat.

Failing to find satisfactory proof of increased oxidation in the loss of weight of the body, or the excessive excretion of urea in fever, attention was then directed to the elimination of carbonic acid, an excretory product which bears a much closer relation to the production of heat than does urea. Immense importance has been justly attached to the determination of the amount of carbonic acid excreted by an individual in fever. No point in the whole battle-ground of fever-pathology has been more hotly contested than whether increased production of carbonic acid is an essential part of the febrile process. The first investigators of this question—Leyden, Liebermeister, Senator—contented themselves with the determination of the amount of carbonic acid eliminated by an individual in fever and in apyrexia. There are several considerations which greatly diminish the value to be attached to the mere estimation of carbonic acid excreted without simultaneous determination of the amount of oxygen absorbed. As has been urged by Senator, and with especial clearness by Pflüger, increased discharge of carbonic acid does not necessarily imply increased production of the same. The discharge of carbonic acid varies, independently of its production, with the rhythm and depth of respiration and with the temperature and the alkalinity of the blood, all factors which are altered in fever in such a manner as to favor increased liberation of carbonic acid. It is true that the influence of these factors would cause increased discharge of carbonic acid out of proportion to its production only for a limited period, and that the prolonged increase in the amount of carbonic acid discharged in fever, which has been found by several observers, can hardly be interpreted otherwise than in favor of increased production. There is another point which detracts still further from the value of exclusive determinations of the quantity of carbonic acid discharged, and this is that it makes a great difference, so far as the production of heat is concerned, whether the carbonic acid is the result of oxidation of carbohydrates, of fats, or of proteids, a difference amounting, according to Rubner, to 29.5 per cent.; or, if only the proteids and fats be considered, to over twenty per cent. In investigations of nutrition, it is now known to be of the utmost importance to determine the so-called respiratory quotient, that is, the ratio between the amount of carbonic acid discharged and that of oxygen absorbed. This quotient varies in a definite way with the kind of material oxidized in the body, and an accurate knowledge of it would enable us to draw conclusions as to the substances consumed in fever.

---

[1] Liebermeister: Handb. d. Path. u. Therap. d. Fiebers, Leipzig, 1875. Leyden: Deutsches Arch. f. Klin. Med., Bd. v.

The investigations which have been published within the last few years upon the absorption of oxygen, as well as the discharge of carbonic acid in fever, are to be ranked as most valuable contributions to our knowledge of fever. The first estimation by trustworthy methods of the amount of oxygen absorbed and of carbonic acid excreted in fever was made in Pflüger's laboratory by Colasanti upon a guinea-pig, and was published in 1877. Since that time two careful and elaborate researches upon this subject have been made, the one by Finkler and the other by Lilienfeld.[1]

These experimenters found that in fever there is increase of the amount both of oxygen absorbed and of carbonic acid excreted. Making comparison with healthy animals, under the same conditions of nutrition, Colasanti found that the increase in the absorption of oxygen amounted to eighteen per cent., and in the excretion of carbonic acid to twenty-four per cent. Finkler, whose experiments were made also upon guinea-pigs, found under varying conditions of external temperature the average febrile increase of oxygen to be 13.8 per cent., and of carbonic acid 13.3 per cent.; and Lilienfeld, who experimented on rabbits, found the average increase of oxygen to be 15.9 per cent. The statement of these averages gives an incomplete conception of the oxidation in fever as they are derived from all stages of fever and varying elevations of temperature. No constant proportion was found to exist between the height of the temperature and the amount of oxidation. On the other hand, a relation was observed between the oxidation and the stages of fever, viz., the initial stage with rising temperature, the acme with constant high temperature, and the defervescence with falling temperature. During the period of rising temperature oxidation was increased, and in this stage Finkler found the highest percentages, amounting to 36.6 per cent. in the increase of oxygen, and 37.6 of carbonic acid. There were, however, marked fluctuations in this stage, both in the temperature and the amount of oxidation. In the stage of constant high temperature, such high percentages were not noticed, and the fluctuations were less marked. The processes of oxidation, according to Lilienfeld, are increased on the average less in the acme than in the initial stage of fever.[2] During defervescence of the fever the increased oxidation falls, and may sink below the normal. Taking a broad view of these stages, we may say, therefore, that the periods of rising, constant, and falling temperatures in fever correspond to the periods of rising, constant, and falling oxidation, but we must bear in mind that the fluctuations in oxidation are much greater than, and bear no constant relation to, those of temperature, so that in each period there are times when oxidation may rise or fall most decidedly without corresponding changes of temperature.

Inasmuch as these experiments have shown that the increased excretion of carbonic acid in fever is accompanied by increased absorption of oxygen, and, as will be explained presently, that the respiratory quotient, if it change at all, sinks, it is evident that we need not discard experiments in which only the amount of carbonic acid excreted has been estimated by good methods. The most accurate of these experiments are those of Leyden and Fraenkel upon fevered dogs.[1] They found that without exception carbonic acid is excreted in larger amount in fever than in health under the same nutritive conditions, the excess amounting sometimes to seventy per cent., and in general being larger than in the experiments which have been previously considered. The earlier and meritorious experiments of Senator upon this point did not give uniform results, and he felt justified in concluding that there is no evidence of increased production of carbonic acid in fever. Subsequent experiments with far more accurate methods have demonstrated the incorrectness of Senator's conclusions. It may be well to call to mind that Burdon-Sanderson's deductions, which have naturally had great influence among physicians here and abroad, were based in great part upon the data derived from Senator's experiments.

Hitherto the methods employed in studying the respiratory gases of human beings in fever have not approached in accuracy those used in the experiments described. If the discordant results of Wertheim, which were obtained by methods manifestly very inaccurate, be discarded, all other investigators have observed augmented discharge of carbonic acid in fever of human beings. Leyden found an excess of fifty per cent. in the febrile discharge of carbonic acid, and Liebermeister, whose observations were made chiefly on cases of intermittent fever, found an excess of thirty to forty per cent. in the period with rising temperature, and of nineteen to thirty-one per cent. in the acme of the fever. During the defervescence of the fever the excess of carbonic acid discharged diminished and sometimes wholly disappeared. In one instance in which the determination was made during the rigor of intermittent fever the carbonic acid excreted was two and one-half times the normal amount, an excess so enormous that it was undoubtedly due in great part to the muscular movements which attended the chill.

Although we cannot consider these figures as absolutely accurate, they indicate clearly that in human beings as well as in animals fever is characterized by increased oxidation, and apparently that, as a rule, in man the excess of oxidation is greater than in the experimental fever of animals. This was to be expected, as it is difficult to produce experimentally in animals anything approaching in intensity the well-marked fevers of human beings.

As the result of these laborious researches, we may consider it established that increased oxidation is a part of the fever-process. It has been claimed that this augmented oxidation is simply the result of the elevation of temperature, but it can be proven that this is not true. Pflüger has demonstrated that the processes of oxidation are more active at high than at low temperatures of the body, and he has also established the increment of oxidation which corresponds to each degree of rise of temperature. By means of these data Finkler has computed that in guinea-pigs the febrile elevation of temperature of 1° C. would cause an increase of the absorption of oxygen of only 3.3 per cent. Moreover, Lilienfeld found decided increase in the processes of oxidation before there was any marked elevation of temperature, and all the experiments have rendered it quite evident that there is no such relation in fever between the height of the temperature and the energy of oxidation as would be expected if the augmented oxidation were merely the result of the increased temperature.

---

[1] Colasanti: Pflüger's Archiv, Bd. xiv.; Finkler, ibid., Bd. xxix; Lilienfeld, ibid., Bd. xxxii.

[2] In the period of rising temperature there was an increase of oxygen absorbed of twenty-seven per cent.; in the acme, of 14.9 per cent.

[1] Leyden and Fraenkel: Virchow's Archiv, Bd. lxxvi.

There is no reasonable doubt that the more energetic oxidation which we find to be an essential part of the process of fever indicates increased production of heat. Exactly what amount of heat-production corresponds to the increased oxidation we cannot know until the kind and the quantity of substances oxidized in fever have been determined. It is to be regretted that no experiments have been made in which the amount of nitrogen excreted has been determined at the same time with the estimation of the oxygen absorbed and of the carbonic acid discharged. These data would enable us to form some estimate, although not an accurate one, of the amount of heat-production corresponding to the oxygen absorbed, unless very different laws from those in health control the oxidation-processes of fever.

Mention has already been made of the importance of determining in fever the respiratory quotient, or the ratio between the carbonic acid discharged and the oxygen consumed. A few words will make this clear. It is well known that under ordinary circumstances in health not all of the oxygen consumed reappears in the carbonic acid discharged. This indicates that a part of the oxygen absorbed is used in other oxidations than those resulting in the production of carbonic acid. According to the extent of these other oxidations, therefore, the respiratory quotient must vary. It is probable that these oxidations, of which carbonic acid is not a product, result, at least in part, in the formation of water, which is therefore one of the excretory products of the body, as has been urged especially by Professor Austin Flint. The influence of various circumstances upon the respiratory quotient has been studied, but what especially concerns us here is that in hunger this quotient sinks, which is to be expected, from the fact that in this condition almost exclusively fats and proteids are oxidized. We evidently possess in the determination of the ratio of carbonic acid discharged to the oxygen consumed a means of reaching a conclusion as to a cardinal point in the pathology of fever, viz., whether the processes of oxidation in fever conform to the laws which govern them in health, and particularly whether, as has been often asserted, unusual or incomplete products of oxidation are formed to any considerable extent in fever. Colasanti and Lilienfeld found that the respiratory quotient in their fevered animals did not vary from that of healthy animals under similar nutritive conditions. Finkler observed that the respiratory quotient fell in fever somewhat more rapidly than in hunger, and this he explains by the more active oxidation in fever. All three experimenters reached the conclusion that the substances oxidized are the same in fever as in health, and that other than the normal products of combustion are not formed in fever in any considerable amount. That the metabolism in fever does differ in at least one important respect from that in hunger is evident from the excessive amount of urea excreted in fever, but considerable variations in the disintegration of albuminous material may occur without much change in the respiratory quotient.

The only determinations of the febrile consumption of oxygen and discharge of carbonic acid in man are those of Wertheim and of Regnard. Both investigators found a decided diminution of the respiratory quotient. The method employed by Wertheim was so defective that no confidence can be placed in his results. The experiments of Regnard[1] are presented with great neatness, but his results on other points differ so much from those obtained by trustworthy physiologists, and by better methods, that we cannot accept his conclusions as to the respiratory quotient in fever without confirmation. Regnard found in all fevers which he studied a most marked diminution of the respiratory quotient. If this were true, it would follow that in fever a much larger part than in health of the oxygen consumed is employed in other oxidations than those yielding carbonic acid. This would confirm the widely accepted belief that water and products of incomplete oxidation are formed in excessive amount in fever.

From the unfortunate discrepancy of these results it is evident that the knowledge which we now possess of the processes of oxidation in fever is not sufficient to enable us to form an accurate estimate of the heat-production. In hunger, from one-fourth to one-third of the absorbed oxygen is available for combination with hydrogen to form water, the remainder uniting with carbon to form carbonic acid (Regnault and Reiset). If in fever the same ratio exists, then the excess of heat production would be proportionate to the excess of oxygen absorbed, assuming that the substances oxidized are the same in both conditions; if, however, as Regnard's experiments indicate, a larger proportion of oxygen is available in fever for the oxidation of hydrogen, then the increment of heat-production would be still greater, for the same amount of oxygen produces more heat when employed in the oxidation of hydrogen than in that of carbon. It is also to be considered that the same quantities of hydrogen and of carbon, in their oxidation, yield varying amounts of heat according to the chemical compounds in which they are contained, and we cannot say positively whether the compounds oxidized are the same in fever as in health, under like conditions of nutrition. Upon the whole, the weight of evidence is in favor of the view that the excess of heat-production in fever is approximately proportionate to the increase in the consumption of oxygen, but it would be rash to assert this positively. It is evident that in fever ordinarily a much smaller amount than in health of the energy resulting from chemical processes is transformed into external mechanical work, so that, relatively, more remains in the form of heat.

In connection with this discussion of the possibility of unusual sources of heat in fever, may be mentioned an hypothesis which has been advanced with much ingenuity by Dr. Ord.[1] This hypothesis is based upon the assumption, which is probable enough, that there are in the body chemical processes in which heat-energy is transformed or rendered latent. These processes are thought to be chiefly those concerned in the building up of tissue. It is argued that inasmuch as the construction of tissue is manifestly in abeyance in fever, the amount of heat in the body may be increased not only by disintegrative processes, but also by "the persistence, in the form of heat, of energy which should have taken another form." That these building-up processes influence decidedly the amount of heat produced in the developing ovum has been demonstrated by d'Arsonval's calorimetrical determination that the egg, during incubation, absorbs heat, notwithstanding the consumption of oxygen and the excretion of carbonic acid. This fact, which might have been predicted, certainly does not justify us in refusing to attach any calorimetrical value to the determination of the respiratory gases and the urinary nitrogen. From the little we know of these constructive processes in human beings, we should infer that the amount of energy in the form of heat which they appropriate bears only a very small ratio to the total heat-energy set free by heat-producing processes, so that their cessation would not bring a large increment to the heat of the body. Moreover, these constructive processes are also in abeyance, although doubtless to a less extent, in starvation, with which experimental fever is usually contrasted, as regards heat-production and heat-loss. It is not probable that any extraordinary difference in the behavior of the processes of tissue-building in fever and in starvation can occur without affecting the respiratory quotient. For the present, therefore, we cannot attach any great importance, so far as the increase of heat-energy in fever is concerned, to the inactivity of heat-absorbing processes.

We have now gone over the evidence which, in my judgment, establishes the fact that there is increased production of heat in fever. The same conclusion is reached also by the study of the loss of heat from the body in fever. That fever is accompanied by increased production of heat, and by more active combustion, has been in all ages the belief of the majority of physicians. This belief, however, has been rather instinctive than based upon actual demonstration. It has been contested by investigators of great ability and on the ground of scientific observations. For these reasons, and on account of the importance of the subject, it has seemed to me desirable to present to you the exact evidence, although many of its details, I fear, may have wearied you. We have learned, moreover, certain facts concerning febrile thermogenesis which the mere observation of fever patients does not render so apparent. We have found that there is no definite relation between heat production and the height of the temperature, so that we may have excessive thermogenesis with low as well as with high temperatures. There appears to be, however, a relation between the stages of fever and heat production, this being in spite of remarkable fluctuations, greatest in the initial stage and least in defervescence. Although, for reasons which have been mentioned, and others might have been adduced, we can attach hardly an approximative value to figures which purport to give the actual heat production in fever, still, unless far more serious errors than seems possible inhere in the methods of direct and of indirect calorimetry, we can draw one important conclusion. This is, that while an individual in fever produces more heat than he would in health, under similar conditions as to food and muscular movements, he does not produce, necessarily, in fever more heat than he would in health on a full diet. And it is certain that he usually produces far less heat in fever than he often does under circumstances which normally increase heat production, such as a cool environment and muscular exercise. That one in health, with little or no change of temperature, may produce twice or more the quantity of heat which he produces in fever, makes it plain that it is impossible to explain febrile rise of temperature simply on the basis of increased thermogenesis, or what probably comes to the same thing, of increased oxidation. That in health vastly increased heat production may occur, with comparatively little change of temperature, is, of course, due to the fact that the dissipation of heat is proportionately increased. It is self-evident, and so far as I know has never been disputed, that in fever the equilibrium is so disturbed that heat loss does not correspond to heat production as it should in health. This disturbance of equilibrium can be brought about in various ways, and it is only by the determination of the actual heat production and heat loss in fever that we can say in what direction the balance is disturbed.

---

[1] Regnard: Recherches exp. sur les Variations pathologiques des Combustions respiratoires. Paris, 1878.

[1] Ord: British Medical Journal, 1885, vol. ii.

We have found that the production of heat is increased in fever when the comparison is made with like conditions of nourishment and of environment. It is obvious that the total loss of heat cannot equal the total production of heat during the period of febrile rise of temperature.

As is well known, most of the heat of the body is liberated from the skin and from the lungs; from the former by radiation and conduction and by the evaporation of moisture, and from the latter by evaporation of moisture and warming the respired air. It has been estimated that in man about eighty per cent. of the total heat dissipation is from the skin.

The method of direct calorimetry already described has been applied only to animals for the determination of the total heat loss in fever. Here Wood's experiments are the best which we possess. Leyden and Liebermeister have furnished calorimetrical data which, although unsatisfactory in many respects, indicate the general direction of febrile heat loss in human beings. All of these experiments show that more heat is dissipated in fever than under like conditions in health. The fluctuations of heat loss during a febrile paroxysm are so great that the statement of an average for the entire period has little significance. Such an average, according to Wood's results on fevered dogs, would fall between twenty to thirty per cent. excess of heat loss as compared with the loss in health under like conditions of food. The dissipation of heat in fever, however, may be at times more than double the normal amount, and again may sink below the normal. We have not sufficiently accurate estimates either of the total amount of heat produced, or of that dissipated, during a febrile attack to enable us to strike a balance between the two. Some persons have been so impressed with the large amount of heat lost during certain periods of fever, that they have concluded that there must be far greater excess of heat production than previous investigations have shown to be probable. They suggest that there are sources of febrile heat of which at present we have no idea. Such conclusions seem to me quite unwarranted when we consider the behavior of heat loss, not for a limited time, but throughout the different stages of a paroxysm of fever. We have already seen that we obtain no satisfactory conception of febrile production of heat unless we follow it during the stages of fever, and this is no less true of heat dissipation. The observation of the condition of the skin, as regards temperature and moisture, must in all ages have afforded an insight into the general behavior of heat dissipation during the different periods of fever. It does not require any instruments of precision to make plain the fact that a cold, dry skin, such as we observe during a febrile chill, liberates less heat than normal; or that a hot, moist skin, such as we are likely to find at the defervescence, loses more heat than normal. Not quite so transparent is the direction of heat loss during the hot stage or acme of a febrile paroxysm or fastigium of a continued fever. Here the skin usually appears hot and dry. The ordinary impression that more heat than normal is dissipated during this stage is supported by calorimetrical experiments. There can be no doubt that the elevation of the cutaneous temperature which we observe in the hot stage of fever causes an increase in the amount of heat lost by radiation and conduction. Similar elevations of cutaneous temperature in health, such as those caused by muscular exercise, are accompanied by increased moisture of the surface. Not only is visible perspiration usually absent during the hot stage of fever, but the invisible perspiration is, as a rule, relatively, although not absolutely, diminished, as Leyden has shown. The dryness of the skin, therefore, is a factor which in the hot stage of a fever tends to lessen heat dissipation. Clinical observation, however, shows that fevers differ markedly from each other as regards perspiration during the hot stage, the skin being sometimes bathed in perspiration without any depression of temperature. It would undoubtedly be of great interest to possess trustworthy data as to the exact loss of water from the surface of the body in different fevers, and at different stages of fever. We cannot place much reliance upon the indications afforded by Weyrich's hygrometer, which has been repeatedly used for this purpose. More is to be expected from the method employed by Peiper[1] in studying insensible perspiration under physiological conditions.

The general impressions regarding febrile loss of heat derived from clinical observations are supported by calorimetrical experiments. The dissipation of heat is least during the initial stage of fever, and greatest during the period of defervescence. During the hot stage or fastigium, heat dissipation exceeds the normal, but usually, on account of the dryness of the skin, not so much as one might infer simply from the impression of heat received by the hand when placed upon the skin.

During the initial period the loss of heat, although on the average less than in the following stages, is usually greater than normal. If, however, the rise of temperature be rapid the heat loss falls below the normal amount. As there is now increased production of heat, there is evidently a glaring disproportion between the two factors, heat production and heat loss, and under these circumstances the febrile attack is likely to be ushered in by a chill. During the febrile chill all the efforts of nature combine to produce in the shortest time the greatest possible elevation of temperature. Not only is heat loss reduced to a minimum, but heat production is excited to the utmost.

---

[1] Peiper: Zeitschr. f. klin. Med., Bd. xii.

During the period of defervescence, on the other hand, the relation between heat loss and heat production is reversed. This is, of course, most apparent when the fever terminates by crisis, with rapid fall of temperature. Then the loss of heat is excessive, being sometimes threefold that in the normal state, and heat production is relatively and often absolutely diminished.

It is of importance to remember that there are continual and irregular fluctuations in the dissipation of heat during the different stages of fever. These fluctuations bear no definite relation either to the momentary production of heat or to the height of the internal temperature. We deal in ordinary life so much more with units of temperature than with units of heat, that it is difficult for us to keep constantly in mind the fact that no inference can be drawn as to the height of the internal temperature from the knowledge of the momentary heat production and heat loss. If the heat loss fall behind heat production the temperature of the body rises, and it can remain at this elevated point, with either diminished or increased heat production, so long as the heat loss equals heat production.

No correct conception of the condition of the heat-regulating mechanism in fever can be obtained without taking into consideration these irregular variations in the discharge of heat, and it is a merit of Senator and his pupils to have emphasized particularly this point. These variations are made apparent not only by calorimetric measurements and direct observation, but also by the studies which have been made of the cutaneous temperature in comparison with the internal temperature in fever. Hankel's law, that the difference between the temperature in the axilla and that of the surface of the body in the febrile condition is less than in the normal condition, manifestly does not hold for the chill, in which it has been proven that the superficial temperature falls while the internal temperature rises. Jacobson, Wegscheider, and Schülein[1] find that there constantly occur, in the course of most fevers, changes of the superficial temperature which stand in no relation whatever to alterations of the internal temperature. Schülein thinks that he has discovered some facts in this regard which are available in diagnosis. However this may be, these observations indicate that contraction and dilatation of the cutaneous vessels are constantly occurring, and without any regularity, in fever. These irregular variations in the calibre of the blood-vessels are also apparent to the eye in the vessels of the rabbit's ear during fever. When it is considered, furthermore, that these irregularities of cutaneous circulation vary decidedly in different situations, no further proof is needed that the mechanism which regulates the discharge of heat from the surface of the body is profoundly disturbed in fever.

These alterations in cutaneous circulation are such striking phenomena that it is, perhaps, not surprising that two great medical authorities should have based upon them exclusively theories of fever—Traube assuming excitation, and Marey paralysis, of vaso-motor nerves as the primal element in fever. We need not discuss these theories, now generally abandoned in their exclusive form. From what has been said concerning the loss of heat in fever, it is evident that we cannot explain febrile rise of temperature solely by the behavior of heat dissipation, any more than we can explain it solely on the basis of increased heat production. In rejecting Traube's theory that fever is the result solely of retention of heat, we must still recognize the fact that decrease in the dissipation of heat, at times absolute, at other periods relative, is a factor of the utmost importance in the febrile process.

From whatever point of view we consider the question, we cannot avoid the conclusion that it is the mechanism which controls the relation of heat production to heat loss which is primarily disturbed in fever.

Heat production is increased in fever, but if the regulating mechanism were normal, then the discharge or heat would be proportionately increased, and the temperature would not be materially affected. Nor would the force of this argument be changed if febrile thermogenesis were twice as energetic as we suppose it to be.

The loss of heat is increased in fever, so that on this ground alone we should be obliged to assume increased heat production. But even if it were proven that heat dissipation is diminished, as has been recently claimed again by Rosenthal,[1] and that fever is the result of heat retention alone, it would still be necessary to admit that the regulating mechanism is at fault; for Pflüger has demonstrated that when this is normal, changes in the temperature of the skin are attended by such changes in heat production that the internal temperature remains, within wide limits, unaltered.

I repeat, then, that the conclusion is forced upon us that the fever-producing agents must act, either directly or indirectly, upon the mechanism regulating the harmonious relation of heat loss to heat production. That the heat-regulating mechanism, although profoundly disturbed, is not entirely paralyzed in fever is proven by the effect of heat and cold upon fevered individuals. Although Colasanti believed that his fevered guinea-pig had lost all power of heat regulation under varying external temperatures, a similar conclusion has not been reached by others who have investigated this question. We can best describe the condition of heat regulation in fever as unstable or ataxic. External cold stimulates, to some extent, the heat production of an individual in fever, but by no means as much as it does in health. A person in fever is not able to retain his bodily temperature under the influence of heat and cold to the same degree that he can under normal conditions. Liebermeister, as is well known, held that heat regulation in fever is simply adjusted for a higher point, although he admits not perfectly adjusted. Experience shows that this so-called adjustment is so unstable that it does not seem proper to compare it with that to normal temperatures in health, so that it is not clear what deep meaning lies in Liebermeister's idea.

We cannot imagine the heat-regulating mechanism to be other than a nervous one.

Some years ago this was about as far as the theory of the mechanism of fever could be carried. All paths led to this mysterious nervous apparatus, and beyond this nearly all was speculation. As has been said, we stood before imposing processes veiled in the deepest obscurity. Since then the veil has been lifted here and there, and we have caught glimpses of the nature of these processes. I refer particularly to the results of researches which have brought to light a more immediate and direct dependence upon nerve energy than had been supposed of chemical processes concerned in the disintegration and construction of tissue, and therefore in the production of heat.

With one side of the nervous mechanism concerned in temperature regulation, the classical investigations of Claude Bernard have made us tolerably familiar. This is the vaso-motor nervous apparatus presiding over the circulation of blood in the superficial parts of the body, and thereby controlling in great measure the discharge of heat. That the important part taken by the perspiration in the dissipation of heat is likewise under nervous influence, has been demonstrated by Luchsinger. The facts concerning this side of the regulation of heat are too well known to require elucidation on this occasion.

Heat regulation, however, is effected not only by variations in the elimination of heat, but also by changes in the production of heat. Familiar as the fact is, it can never cease to arouse our admiration that the temperature of the body remains the same in cold and in warm atmospheres. Man has become so dependent upon clothing that in the naked condition his capacity of preserving his normal temperature in a cold environment is much less than that of most animals. Pflüger has demonstrated that the heat regulation under varying external temperatures is accomplished by changes both in heat production and in heat loss, so that in a cold atmosphere more heat is produced, and in a warm atmosphere less heat, provided the external temperature is not so high or so low as to make it physically impossible to preserve the body temperature. It is evident that this is the most rational and economical method of retaining the internal temperature of the body. To regulate the body temperature simply by variations in the discharge of heat, as was formerly supposed to be the method, would be, as has been said, like regulating the temperature of our rooms summer and winter by opening and shutting the windows without controlling the source of heat.

---

[1] Jacobson: Virchow's Archiv, Bd. lxv. Schülein: Ibid., Bd. lxvi. Wegscheider: Ibid., Bd. lxix.

[1] Rosenthal: Deutsche med. Wochenschrift, 1888.

A heat-producing or thermogenic apparatus, therefore, is no less a part of the heat-regulating mechanism than is the heat-discharging or thermolytic apparatus, to use the terms employed by Foster. As the thermogenic apparatus is less generally understood, it is not permissible to dismiss its physiology in this connection so briefly as I have the thermolytic, although our knowledge of the former is very imperfect.

I can assume that the convincing reasons are known to you which have led physiologists to conclude that most of the animal heat is produced in the muscles and the glands, and that the muscles have the larger share in this function. It is also well known that stimulation of secretory and motor nerves causes not only visible physical alterations in the glands and muscles, but also production of heat. This sort of dependence of heat production upon innervation has been long admitted. It may, however, not be so generally known that there are reasons to believe that nervous impulses control chemical changes which result in the production of heat, independently of visible physical alterations of the tissues; in other words, that heat production or thermogenesis is at least in considerable part under the immediate and direct control of the nervous system. The idea is not a new one, and was advocated especially by Claude Bernard. Recent discoveries, however, have given it unexpected support.

This subject of the relation of innervation to thermogenesis is most pertinent to the pathology of fever, but it is essentially a physiological one, and as I wish to confine to a single lecture what I have to say concerning the theory of fever, it is impossible for me to do more than summarize the most essential points belonging here. This I can do the more readily as Dr. MacAlister,[1] in his admirable Gulstonian Lectures on the nature of fever, which were delivered last year, has clearly and forcibly presented the main facts.

The larger part of these facts relate to the chemical changes and heat production of muscles under varying conditions.

That a large part of the chemical changes in a muscle in the condition which we call repose is under the influence of the nervous system is made apparent by the great diminution in its consumption of oxygen and formation of carbonic acid which follows the separation of the muscle from all connection with the central nervous system. This is conclusively shown by the experiments of Bernard, Pflüger, Von Frey, and others. It is, of course, possible, and it has generally been supposed that, under these circumstances, it is simply the withdrawal of motor impulses which lowers the heat-producing energy of the muscle. Far more suggestive as regards the point under consideration are the results of investigations which have been carried on in Ludwig's laboratory by Meade Smith, MacAlister, and Lukjanow. These experimenters have shown that heat production and contraction are in a measure independent properties of the muscle. By various influences the thermogenic property may be so impaired that a stimulus causes contraction with scarcely any development of heat. The laws governing the restoration and the fatigue of the thermogenic function differ from those controlling the mechanical function. These researches, upon which I here only touch, have made it extremely probable that there are in the muscle chemical processes resulting mainly in the production of heat, and chemical processes causing mainly contraction, and that these processes, although co-ordinate, are not identical. A new light is shed upon the meaning of the term chemical tonus of muscle, which has for some time been used by some physiologists. Great caution is properly exercised by Ludwig and his pupils in the interpretation of these interesting results. They do not infer from them, necessarily, the existence of so-called thermic or calorific nerves. They suggest that it is possible to explain the phenomena upon the supposition that there are in the muscle two kinds of material, thermogenic and contractile, and the nervous impulses acting upon these may pass through the same set of nerves. Proof of the existence, in connection with muscles, of thermic in distinction from motor nerves, would be afforded if we could succeed, after paralysis of the motor nerves, in exciting by nerve-stimulation the thermogenic function of the muscle. We possess in curare a drug which paralyzes the terminations of the motor nerves. Meade Smith attempted by its aid to determine whether possible thermic nerves may be differentiated from motor, but he reached no positive conclusion on this point. There are, however, on record some observations which suggest the possibility that in moderate doses curare may leave intact thermic nerves after the suspension of the function of motor nerves. When an animal is profoundly under the influence of curare the internal temperature falls, and the processes of oxidation are greatly reduced. The animal is no longer able to resist the changes of external temperature, its own temperature rising and falling like that of a cold-blooded animal when exposed to heat or cold. This effect of curare-poisoning is another proof of the dependence of heat production upon nervous influences. Claude Bernard, in his early researches on the action of curare, noted elevation of temperature soon after its administration. Recently, U. Mosso[1] claims that an animal may be placed so far under the influence of curare as to paralyze completely the voluntary muscles, and the internal temperature either remain normal or rise. He infers that these moderate doses of curare, although sufficient to paralyze the motor nerves, must have left intact the thermic nerves. That rise of internal temperature is not due to retention of heat, he thinks is evident from the normal or elevated temperature of the skin. Mosso is strengthened still further in his conclusion as to the existence of thermic nerves by finding that, after complete paralysis of the motor nerves by curare, injections of strychnine cause an elevation of rectal temperature which may amount to three degrees centigrade. Under these circumstances strychnine produces no spasms or other visible mechanical effect upon the muscles. Mosso brings forward a number of other experiments (decidedly open to criticism) intended to demonstrate the existence of nerves directly controlling heat production, but those which I have mentioned are by far the most striking. It seems to me that the natural interpretation of these experiments is in favor of the view that there are nerves controlling heat production in the muscle distinct from motor nerves. Far more conclusive, as to thi spoint, than thermometric observations, would be calorimetric experiments determining the heat production of animals under varying doses of curare.

This whole line of experimentation, directed toward the differentiation of the mechanical and the chemical functions of muscle, is certainly most suggestive, but so long as the interpretation of the results is not perfectly clear we should be very guarded in drawing far-reaching conclusions. I cannot refrain, however, from pointing out that, as mentioned by MacAlister, all of these thermogenic phenomena may be found eventually to depend upon nerves whose chief function, on the one hand, is the disintegration, the katabolism of tissue, and, on the other hand, the restoration, the anabolism of tissue. From the study of the electrical changes which stimulation of the pneumogastric nerve produces in the heart-muscle Gaskell concludes that this nerve puts the heart in a condition of relative rest, during which the energy of the muscle is increased. During this period there is reason to believe that the material of the muscle, which when disintegrated gives rise to heat and mechanical work, is in the process of restoration. Hence, Gaskell speaks of the pneumogastric or inhibitory nerve of the heart as anabolic—that is, it directs the restorative, formative, anabolic processes in the muscle. On the other hand, the accelerator nerve of the heart induces the opposite electrical changes in the heart-muscle. Gaskell describes this nerve as katabolic—that is, its stimulation causes disintegration of the muscle materials, and liberates energy in the form of heat and of mechanical work. If it be found that similar inhibitory and accelerator nerves preside over the chemical changes in the voluntary muscles and other tissues of the body, then Gaskell's induction as to the existence of anabolic and katabolic nerves must be regarded as one of the most important and profound in modern physiology. Thermo-excitory nerves we should then rank as katabolic, thermo-inhibitory as anabolic.

[1] Mosso: Virchow's Archiv, Bd. cvi.

These investigations, tending to demonstrate the independent existence of thermogenic properties in the muscles, and possibly of nerves directly controlling thermogenesis, have prepared us for the consideration of the relation of the central nervous system to the heat producing properties of the body. Here you will willingly permit me to confine my remarks to the more essential and best established facts, without entering into a full discussion of one of the most perplexing subjects in the physiology of the nervous system.

The clinical basis of the doctrine that lesions of the central nervous system influence directly the temperature of the body was laid by Sir Benjamin Brodie, who reported the well-known case of fracture of the cervical vertebræ and injury of the spinal cord, followed within a few hours by a rise of temperature to 111° F., measured between the scrotum and the thigh. Since then many similar instances have been reported. It is well to remember, in framing theories on the basis of these cases, that there are also on record not a few instances in which apparently similar injuries of the same parts of the spinal cord have been followed by equally striking fall of temperature.

The experimental basis for the acceptance of an influence of the nervous system on temperature was laid by Bernard in his celebrated experiments on the effects of division of the sympathetic nerve in the neck. Bernard interpreted the increased temperature of the ear following this operation as referable, not only to the larger amount of blood in the part, but also to increased tissue metamorphosis and consequent heightened heat-production. The latter part of this interpretation is not generally accepted. It may be said here that the common idea that an organ or tissue, simply because it receives a larger supply of blood, indulges in more active metabolism, is opposed by the investigations of Pflüger, who finds that the amount of oxygen taken up by the cells depends in a far higher degree upon the state of their innervation at the time than it does upon the supply of oxygen. The demand of the tissues for oxygen is not increased simply because the supply is greater. The arguments upon which Pflüger bases this line of reasoning, although not without opposition, would dispose of the idea that when any considerable increase of heat-production in the muscles occurs, this can be explained simply by vaso-motor changes. I mention this here because the opinion has been advanced that a large part of the increased production of heat in fever, and after certain injuries to the nervous system, is referable simply to vaso-motor changes in the muscles.

In 1866 Tscheschichin[1] published experiments which he interpreted as indicating the existence in the brain of centres which, when irritated, moderate the production of heat, and which he called heat-moderating or heat-inhibitory centres, and in the spinal cord of centres which, when stimulated, excite the production of heat, heat-excitor centres. These conclusions were not justified by the experiments, but they have been widely accepted.

I may say here that in this connection I use the term heat-centres as a convenient and generally adopted one. There is a proper reaction against the prevailing misuse of the word " centre " for all sorts of little understood localization of nervous functions. It would undoubtedly be more accurate to use some such expression as thermically active region, instead of heat-centre.

It is not easy to reconcile the clinical fact that in human beings lesions of the spinal cord may be followed at once, or in a very short time, by extraordinary elevations of temperature with the results of experiments on animals. That the rise of temperature in human beings is not due to inflammatory fever is apparent from the rapidity with which it follows the injury. It cannot be explained by vaso-motor lesions, for the paralysis of the vaso-motor nerves accelerates the discharge of heat from the surface of the body. The high temperature can be explained on Tscheschichin's assumption. The lesion either directly stimulates the spinal thermogenic centres or removes the influence of the thermo-inhibitory centres. These clinical observations are the strongest support which has been found for the belief in the existence of centres in the spinal cord which accelerate heat production. Section of the cervical part of the spinal cord in a dog or a rabbit is, under ordinary conditions, always followed by a rapid fall of the internal temperature and diminished oxidation.

These varying results in man and in animals have been explained by supposing that after section of the cervical cord, on the one hand, the discharge of heat is increased by dilatation of the superficial blood-vessels in consequence of vaso-motor paralysis, and, on the other hand, the production of heat is increased by withdrawal of thermo-inhibitory cerebral impulses. If, as ordinarily happens in dogs and smaller animals, the first factor predominates, then, in consequence of sinking of the internal temperature, the heat-producing processes are so reduced that the influence of the second factor is not manifest. The attempt has been made to test this explanation by placing the animal, after section of the cord, in a warm atmosphere. If thereby the heat discharge be reduced to a minimum, it is found that the internal temperature of the animal with severed cord rises more rapidly than that of a normal one under the same external conditions. Here thermometric observations are not conclusive as to the point to be tested, for the more rapid rise can be explained simply by failure of the heat-regulating mechanism. Wood's calorimetric experiments, however, seem to show that there is greater heat-production under these circumstances in the animal with cut cord. These experiments admit of various interpretations, but if they be regarded as establishing the assumption from which we started, then it is evident that in man and in large animals the increased heat production after injury of the cord would not be so readily overcome by the increased discharge of heat from the surface, for in proportion to its volume a large animal has less surface than a small one. The interplay, therefore, of those opposing tendencies might cause different results, according to the size of the animal.

Tscheschichin found that a transverse section made at the junction of the pons and medulla oblongata is followed in a short time by rise of internal temperature. As the superficial temperature is also elevated, he concludes that there is no retention of heat; moreover, the section is made above the dominant vaso-motor centre. Wood has shown, by means of the calorimeter, that after this operation there is actual increase in the production of heat. He, as well as Tscheschichin, interprets the experiment as indicating thermo-inhibitory centres above the lower border of the pons. Bruck and Gunter[1] repeated and modified these experiments under Heidenhain's direction. Out of seven cases in which they separated the pons from the medulla, they observed only in two rise of temperature; of eleven cases in which they punctured the pons with a needle, in five they noted increased temperature. Heidenhain thinks these experiments indicate heat-exciting, rather than heat-moderating centres, and it must be admitted that the evidence is not conclusive in support of either view.

---

[1] Tscheschichin: Reichert u. Du Bois-Reymond's Archiv, 1866.

By far the most interesting and conclusive experiments showing the influence of the central nervous system on thermogenesis are those of Isaac Ott, followed by Richet, Aronsohn and Sachs, Baginsky and Girard.[2] The observations of Ott, Richet, and Aronsohn and Sachs were made independently, and at about the same time, but Ott was the pioneer. The experiments of Aronsohn and Sachs are reported with especial fulness and detail. These investigators find that if the skull of a rabbit be trephined at the junction of the coronal and sagittal suture and a needle be passed vertically down so as to puncture the anterior part of the caudate nucleus near its median convexity, there follows a rise of body-temperature which may amount to three degrees or more, and which may persist for two or three days. The rapidity and the duration of this elevation of temperature vary somewhat with the depth of the puncture, parts immediately beneath the caudate nucleus being also thermically active. Puncture of the overlying cortex or medullary substance has no such effect upon temperature. With the exception of some increase in the frequency of the respiration and of the pulse, the animal, after puncture of the anterior median part of the caudate nuleus, presents no abnormal symptom other than the rise of temperature. I have several times repeated this experiment, and always with the result described. That the pyrexia induced by puncture of the caudate nucleus is not due to vaso-motor changes causing retention of heat is proven by Richet's and Ott's calorimetric experiments and by the determination by Aronsohn and Sachs that the consumption of oxygen and the elimination of carbonic acid and urinary nitrogen are increased. Aronsohn and Sachs and Girard find that electrical stimulation of the anterior median part of the caudate nucleus causes the same thermic phenomena as the puncture, and they therefore conclude that this region contains a thermo-excitor heat-centre. This is the natural interpretation of their experiment, although Baginsky and Ott regard the centre as thermo-inhibitory on grounds which cannot be considered convincing.

Ott claims that there are four cerebral heat-centres: One about the corpus striatum, the second in the caudate nucleus, the third in the anterior inner end of the optic thalamus, and the fourth near the median line between the optic thalamus and the corpus striatum. The greatest rise of temperature he found after injury of the thalamic centre.

No adequate demonstration has been afforded of any influence of the cerebral hemispheres upon thermogenesis. Corin and Van Beneden[3] find that pigeons, after removal of their cerebral hemispheres, exhibit no change of temperature, no failure of the heat-regulating mechanism, and no alteration in the excretion of carbonic acid.

I have endeavored to present to you the main physiological facts bearing upon the relation of the nervous system to thermogenesis. It must be admitted that we are left to surmises as to the interpretation of many of the facts, and particularly as to their connection with each other. But certain important points come out clearly. We have found evidence of the existence in the body of chemical processes resulting chiefly in the production of heat energy. We have learned that these processes are under the direct control of the nervous system, and possibly of nerves distinct from those now recognized as motor or secretory. We have seen that there are regions in the central nervous system which are doubtless in some way connected with these nerves, and through them control the chemical processes resulting in the production of heat.

The bearing of these facts upon the theory of fever is evident. The study of heat production and of heat loss in fever has led us, by arguments which need not be repeated, to the conclusion that the pyrogenic agent must in some way act upon the heat-regulating mechanism. The study of this mechanism, more particularly of its thermogenic side, affords some insight into the manner in which the fever-producing agent may affect the regulation of heat. The main difficulty in the neurotic theory of fever has been to understand how, by any action of the fever-producing agent directly upon the nervous system, the chemical processes leading to heat production could be stimulated. I have dwelt thus at length upon the innervation of thermogenesis, to show that this difficulty has been overcome. To some it seems more reasonable to suppose that the pyrogenic agent circulating in the blood acts directly upon the tissues, altering and stimulating their chemical changes. This is the hæmic theory, which, in some form, has always stood over against the neurotic theory of fever. Although it may at first glance appear simpler, the hæmic theory is really the more complicated, for it has already been set forth that we cannot explain fever simply by increased heat production; so that, even if the primary effect of the fever agent were upon the heat-producing processes, there must be a secondary influence upon the nervous system, for heat dissipation is no less disturbed than heat production.

If an animal be thoroughly curarized, so that no impulses from the nervous centres can reach the muscles, the great heat producers, then it is found to be impossible to produce febrile elevation of temperature by the injection of pyrogenic agents. This fact, first demonstrated by Zuntz, is justly held to weigh heavily in favor of the neurotic theory of fever.

Contrary to the results of Murri,[1] I have not been able to induce rise of temperature or check its fall by the injection of pyrogenic agents into the jugular veins of dogs whose spinal cords have been cut in the lower cervical region. In these experiments I have employed various pyrogenic agents, and especially pepsin and papoid. One specimen of the latter which I used possessed very striking pyrogenic properties.

The pyrexia produced by puncture of the caudate nucleus, in the manner already described, possesses all of the essential properties of fever, regarded as abnormal elevation of temperature. In this experimental condition there are increased production of heat, increased dissipation of heat, excessive elimination of urea and of carbonic acid, and excessive absorption of oxygen. The breathing and the pulse are increased in frequency. The elevation of temperature (usually after a brief fall) begins within half an hour after the puncture, attains a febrile height, and persists sometimes for days. As no observations exist as to the heat regulation of these animals, I have made experiments on rabbits, after puncture of the caudate nucleus, by placing them in a cold environment and in a box heated to various temperatures, and I find that their power of temperature regulation is less than that of normal animals. These animals, in a word, present all of the essential symptoms of fever, and I do not know why we should not call the condition fever. If so, we must admit that injury to a circumscribed, definite region of the brain is capable of causing fever. This experiment, therefore, is of the greatest importance in support of the neurotic doctrine of fever. It indicates, of course, that we may have fever of purely nervous origin without any pyrogenic agent in the blood. This experimental evidence is supported by the clinical cases collected by White in "Guy's Hospital Reports" (1884). It is to be hoped that, by careful thermometric study of focal brain and cord lesions, a more accurate idea may be reached than is now possible of the topography of the thermically active regions in the central nervous system of man.

[1] Murri: Teoria della Febbre. Fermo, 1874.

Admitting the dependence of fever upon the nervous system, I do not regard as particularly profitable, with our present knowledge, the discussion as to whether febrile thermogenesis is excited by the withdrawal of thermo-inhibitory impulses, or by the stimulation of thermo-excitory nerves or nerve-centres. If we regard, and there are forcible arguments for doing so, the heat inhibitory nerves as anabolic, and the heat-exciting nerves as katabolic, then, inasmuch as the formative or anabolic processes are manifestly in abeyance in fever, we can reasonably infer that the function of the heat inhibitory nerves is impaired. The phenomena of the febrile chill, in which both the contractile and the thermogenic properties of muscle are stimulated, speak strongly in favor of direct irritation of the heat-exciting nerves in fever. We might infer, therefore, that both sets of nerves are affected.

But my aim in this lecture has been not so much to construct a theory of fever—a theory which, although it may be useful, must necessarily be largely speculative if it be coherent and rounded—but to bring before you the main facts concerning heat production, heat loss, and heat regulation in fever, and to point out the physiological basis on which their solution is to be expected.

Doctors in Politics.—The "organ" of a Philadelphia medical college says: "The medical legislator is not usually a pleasant figure to contemplate. The methods of 'practical politics' are so degrading that the physician of high standing is seldom found who will stoop to their employment. The doctor who has attained eminence in this field is scarcely to be found." Now this is demonstrably untrue. At the head of medical men in legislatures stands the renowned pathologist Virchow, who, amid the herculean labors which have resulted in the vast pathological treasures with which he has enriched the science of medicine, has been able to carry on a fight for individual rights and good government against the monopoly socialism of Bismarck and the mobocratic socialism of the social democrats. The history of the United States is full of similar illustrative instances of the value to a community of medical men taking part in politics. Foremost among the signers of the Declaration of Independence were Drs. Josiah L. Bartlett, of New Hampshire; Lyman Hall, of Georgia; Matthew Thornton, of Massachusetts; Benjamin Rush, of Pennsylvania; and Oliver Wolcott, of Connecticut. Dr. Cadwallader Colden, of New York, was prominent among those who guided New York during and after the Revolution. His work on botany was adopted by Linnæus as an authority on American botany. It is a striking fact that the very physicians who decry interference in politics by medical societies and medical men, are the first to use social influences to force politicians to appoint them to medical positions, or to aid them in securing dispensary subsidies for the "clinics" of diploma-mills. In the American Government the interference of the physician as a physician has always proved beneficial. —*Medical Standard.*

A CLINICAL PAPER ON PYLORIC STENOSIS DUE TO ULCER—ON ACUTE INTUSSUSCEPTION IN AN ADULT, WITH SPONTANEOUS REDUCTION—ON PARALYSIS OF THE LARGE INTESTINE FROM TUBERCULAR ULCERATION, SIMULATING ACUTE GENERAL PERITONITIS.[1]

By FRANCIS KINNICUTT, M.D.,

PHYSICIAN TO ST. LUKE'S HOSPITAL AND THE NEW YORK CANCER HOSPITAL.

The clinical cases which are recorded in the present paper have been selected as presenting points of interest both to the physician and the surgeon.

I. Dilatation of the Stomach from Pyloric Stenosis, the Result of Ulcer.—In November, 1886, I was asked to see a gentleman who had recently arrived in New York. The following history was obtained from the patient: For the past ten years he had been almost a constant sufferer from severe digestive disturbances. Five months previous to the date of consultation he had vomited blood on a single occasion, but he was unable to state whether there had been earlier hæmatemesis.

During the past two months all his symptoms had been aggravated; there had been much epigastric distress, pain, and vomiting, and for six weeks he had been unable to retain any food, vomiting occurring almost immediately after its ingestion. The vomited matter was frequently of a grumous consistence and of a dark-brown color. He had also been troubled greatly by acid eructations and obstinate constipation.

On examination the patient was found to be greatly emaciated, weak, and suffering from the symptoms described above. The contour of the stomach was plainly visible through the thin abdominal walls, the lower boundary reaching a point four inches below the umbilicus in the median line.

There was marked succussion on palpation, and even on any voluntary movement of the body by the patient. A feeling of resistance was detected at the normal site of the pylorus, but the stomach was so distended as to preclude an opinion in regard to the existence of a tumor. All fluids and solid food by the mouth were prohibited, and rectal alimentation ordered. At the expiration of forty-eight hours the contents of the stomach were withdrawn by a stomach-tube, and were found to consist of a discolored fluid, of an intensely acid reaction, containing undigested remnants of food, with a small amount of mucus and hæmatin. An examination of the abdomen immediately afterward distinctly revealed the presence of a tumor, the size of an English walnut, at the usual site of the pylorus. It was firm to the feel and immovable.

Dilatation of the stomach from pyloric stenosis evidently existed. The nature of the obstruction admitted of doubt; the history of the case, the small size of the tumor, with the great dilatation, which had evidently existed for a very considerable period, and finally the hypersecretion and hyperacidity of the gastric juice, led me to express the *belief* that a pyloric ulcer, with stenosis dependent upon its partial cicatrization, or upon hypertrophic changes, was present rather than malignant disease. During the subsequent fortnight the patient's strength rapidly failed, and the emaciation reached a degree rarely seen. Any attempt to feed the patient by the mouth was followed by great distress and vomiting. Lavage was employed, but failed to afford any relief. A hypersecretion of the gastric juice, independent of the presence of food, was demonstrable by the withdrawal of a considerable quantity of a clear, intensely acid fluid, containing free hydrochloric acid, at intervals of two, three, and four days after the ingestion of food of any kind by the mouth. Death occurred on the fifteenth day from the date of my first visit to the patient.

I am indebted to Dr. Ferguson for the following notes of the necropsy: On opening the abdomen and examining the stomach *in situ*, it is found to be greatly dilated; a tumor, the size of a pigeon's egg, hard to the feel, is present at the pylorus. On opening the stomach, its walls appear to be hypertrophied, especially so in the pyloric region. A circular ulcer, two centimetres in diameter, extending through all the coats to the serous covering, is present at the pylorus, in the line of the lesser curvature. The ulcer is only fully exposed to view by incising the pylorus. A band or cord of adhesion extends from its site to the undersurface of the right lobe of the liver, in the neighborhood of the gall-bladder. The edges of the ulcer are thickened and the pylorus is contracted, admitting no more than the tip of the little finger. By the adhesion of the pylorus to the liver, the duodenum is bent at an acute angle upon the former, still further occluding the outlet of the stomach. The remaining viscera do not present any noteworthy pathological changes.

---

[1] Read before the Practitioners' Society, March 2, 1888.

Histological examination reveals a moderate degree of fatty degeneration of the epithelial lining of the gastric tubules, especially marked in the pyloric region. In the tissues immediately surrounding the ulcer there is a zone of infiltration, with small round cells. There is a marked increase in the intertubular connective tissue at the pyloric extremity, and the muscularis mucosæ is greatly thickened.

Remarks.—The presence of hypersecretion, with hyperacidity of the gastric juice, in the present case is a pathological condition which obtains very constantly in gastric ulcer, and is of interest from an etiological stand-point.

That hyperacidity may well be a factor in the pathogenesis of gastric ulcer, and an obstacle to repair, may be granted; that it is primary, that it alone may suffice to produce ulcer, as Reigel claims, may certainly be questioned. In cases both of cicatricial and hypertrophic stenosis, I believe, as a rule, the existence of a small tumor can be detected. The thinness of the abdominal walls which usually obtains in these cases facilitates physical exploration. In five cases of pyloric stenosis of the above nature, which have fallen under my observation during the past two years, a pyloric tumor was easily detected in all.[1]

My comparatively limited experience also leads me to believe, contrary to the opinion of several authorities, that the mobility of the tumor may afford some clew as to the presence or absence of adhesions. In two of the above cases the tumor was freely movable, and adhesions proved to be absent; in two the tumor was fixed, and firm adhesions were discovered at the necropsy.

A practical question naturally suggests itself in connection with the case which has been described: Can medical or surgical skill avail to relieve suffering and considerably prolong life in pyloric stenosis of this degree, by whatever cause produced?

Among therapeutic measures, lavage alone may temporarily ameliorate some of the more distressing symptoms, but it fails to avert a painful death by gradual inanition. A review of the results obtained by surgical operations will be of interest. In a very complete paper by Winslow, on "Pyloric Stenosis," published in the *American Journal of the Medical Sciences* (April, 1885), the various surgical operations which have been devised for the relief of this condition are described in detail, and a statistical summary is given of all cases of resection of the pylorus, of gastro-enterostomy, and of digital divulsion recorded to February 1, 1885. In this summary the pylorectomies number sixty-one, performed in various quarters of the globe, with sixteen recoveries—23⅔ per cent.

In fifty-five cases the operation was performed for cancerous disease, in five for idiopathic ulcer, and in one for stenosis due to swallowing caustic soda. Eleven of the sixty-one resections were performed by Billroth, with six recoveries—54½ per cent. In two of his successful cases five inches were removed from the greater curvature. In the six cases of stenosis due to ulcer and non-malignant causes, there were three recoveries—50 per cent.—and the cure was apparently radical. In the same summary are found records of thirteen gastro-enterostomies, and of six cases in which digital divulsion of the pylorus, after Loreta's method, was practised.

The proportion of recoveries in the former was about 30¾ per cent.[1] In eleven of the cases the disease was carcinoma; in one stenosis of the duodenum, due to ulcer, existed; and in one pyloric stenosis, caused by swallowing sulphuric acid. In the six cases in which digital divulsion was performed, the stenosis was cicatricial in character and due to ulcer. The percentage of recoveries was 60 per cent., and in these the relief was almost immediate, and the cure apparently a permanent one.

From February 1, 1885—the date of Dr. Winslow's summary—to January 1, 1888, I have been able to collect the records of twenty-four cases of resection of the pylorus, and of twenty-two gastro-enterostomies. The summary is necessarily an incomplete one, but it embraces all the cases reported in accessible literature.

In the twenty-four cases in which pylorectomy was performed there were eleven recoveries and nine deaths, the result being unknown to me in four cases.

Four of the twenty-four cases were operated upon in Billroth's clinic during the year 1887. In three the stenosis was due to cicatricial contraction from ulcer. Recovery followed the operation in two of the cases; death in one. In the former, 6.5 ctm. and 2.5 ctm. of the lesser curvature, and 4.0 ctm. and 8.5 ctm. of the greater curvature, respectively, were removed.

In the fourth case, which recovered, sarcoma, involving the anterior and posterior walls of the stomach, was present. Five centimetres of the lesser curvature and 18 ctm. of the greater curvature were removed.

The proportion of recoveries in the twenty-two cases in which gastro-enterostomy was performed was 50 per cent. In eighteen of the twenty-two cases the disease was carcinoma, and there were seven recoveries. In two cases the stenosis was due to ulcer, and recovery followed the operation in each. In one case tubercular stricture was present; the operation was successful; the patient died, however, four months later, of tuberculosis.[2]

I have only been able, with the literature at my disposal, to find the records, since 1885, of three cases in which digital divulsion has been performed, with two deaths and one recovery. They were all cases of stenosis, due to ulcer. A statistical summary, embracing, I believe, a number of other cases of digital divulsion, which has lately been published in Italy, will soon be accessible to complete the present record.

The following conclusions may be drawn from a study of the results obtained up to the present time by surgical operations for the relief of pyloric stenosis.

1. That the mortality incident to the operations, both of pylorectomy and gastro-enterostomy, although still very high, has apparently decreased with an increased knowledge of, and skill in, the technique of the operations.

2. That in cancerous disease they offer the possibility of at least temporary relief from suffering, and oftentimes of a very considerable prolongation of life; that recurrence occurs no sooner than in cases of cancerous disease elsewhere situated, in which the growth has been removed by surgical operations, and that such recurrence rarely causes renewed obstruction.

3. That the percentage of recoveries, both in resections of the pylorus and in gastro-enterostomies, is much higher in cases of stenosis due to non-malignant than to malignant disease.

4. That the recoveries in the former cases are usually permanent.

---

[1] In four of the cases a necropsy was obtained, and the diagnosis confirmed. The fifth case is still under observation. There is, however, a typical clinical history of gastric ulcer, extending over a period of several years, and of a gradual dilatation of the stomach.

[1] The result in one case was unknown.

[2] In one case the nature of the obstruction is not mentioned.

II. ACUTE INTUSSUSCEPTION IN A MALE, AGED FORTY, WITH SPONTANEOUS REDUCTION.—Mr. B——, aged forty, had noticed a slight irregularity of the bowels for two days, consisting of two or three loosish movements daily, unaccompanied, however, by pain. On the morning of November 17, 1887, he had a copious, painless, semifluid stool immediately on rising. It was followed by a slight feeling of abdominal discomfort, and an hour and a half later by a second movement, watery in character, and accompanied with very considerable "straining." With the effort he was suddenly seized with agonizing pain, distinctly localized to the right of and below the umbilicus, and accompanied with vomiting. The pain recurred in paroxysms every two or three minutes. Mr. B—— was seen by me an hour later. The patient was in a state of partial collapse, he was sweating profusely, the temperature (in the mouth) was 97.3° F., the pulse small and feeble, the extremities cold. He was suffering acute pain, sharply localized over a region midway between the umbilicus and the right anterior superior spinous process of the ileum. On examination, a tumor the size of a small egg could be distinctly felt in the diagonal line above mentioned. Over its site there was dulness on percussion and sensitiveness on palpation. Exquisite paroxysms of pain were produced by manipulation of the tumor. Fifteen minims of Magendie's solution were given hypodermatically in the course of twenty minutes, with only very partial relief of the patient's suffering. Examination two hours later: The tumor has distinctly increased in size, the pain is still very acute, although the patient is well under the influence of the morphine administered. The temperature is still subnormal and the pulse feeble. No further movement of the bowels has occurred, and there is no tenesmus. A large enema of water was given, which was passed, slightly discolored, shortly afterward. A second enema was administered, with similar results. Examination three hours later: The patient's condition is much the same, the pain is still acute, paroxysmal in character, and localized over the same region. The patient dreads physical examination. There has been no movement of the bowels, and no more than two ounces of urine have been passed during the past twelve hours. Dr. William T. Bull, who kindly gave me the advantage of his counsel, agreed with the diagnosis of an acute intussusception. It was determined to employ further enemata of water, and additional morphine during the night, and, on their failure to produce relief, to advise immediate laparotomy. Before the administration of either the patient fell asleep, and an hour later awoke, declaring himself wholly relieved from pain and "well." Careful examination failed to reveal a trace of the tumor which had been present two hours previously, and, beyond a feeling of general abdominal soreness, all physical signs had disappeared. A small dose of morphine was given hypodermatically. The patient slept well and quietly during the night, and awoke feeling much as usual. A further examination confirmed the results of that of the previous night. Later in the day, there having been no movement of the bowels. a simple enema of water was given, with the effect of producing two copious, markedly bloody stools. From this date there were no further symptoms, with the exception of the occurrence of a third slightly bloody movement of the bowels.

Remarks.—The group of symptoms, viz., the sudden onset with straining at stool, preceded by an irregularity of the bowels, the very acute pain distinctly localized and paroxysmal in character, the presence of a well-defined tumor, and, finally, the sudden disappearance of all symptoms coincident with that of the tumor, and the subsequent passage of bloody stools, presents a typical clinical picture of an acute intussusception. From the position of the tumor it would seem probable that the intussusception was either of the ileo-cæcal or ileo-colic variety. The absence of tenesmus may be explained by the height of the portion of the gut involved.

A study of the case would seem to justify the opinion that a spontaneous reduction of the intussusception occurred. That this mode of termination is extremely rare, and probably impossible, except in quite recent cases, must be admitted. The enemata employed cannot be considered as a factor in the reduction, as an amelioration in the symptoms and the disappearance of the tumor only occurred several hours later; the influence of the morphine administered was apparently the indirect one of producing a state of nerve-repose.

III. ACUTE PARALYSIS OF THE LARGE INTESTINE, DUE TO TUBERCULAR ULCERATION, SIMULATING GENERAL PERITONITIS.—A. W——, aged thirty-four, housemaid, was admitted to my wards in St. Luke's Hospital, March 11, 1887. The patient's mental condition on admission was such that no history of her illness was obtainable. The following facts were elicited from her friends immediately previous to her death: The patient had enjoyed good health previous to three months before admission to hospital. At about this date she had "caught cold," and had been troubled with more or less cough up to the present time. For the past two weeks she had vomited after the ingestion of food of any kind, and had complained of severe and continuous pain in the abdomen, which had gradually increased in acuteness up to the date of admission. There had also been obstinate constipation, but it was impossible to obtain more exact information as to the date of the last movement of the bowels than that there had not been one for "several days." For a week, the patient had been "queer and a little out of her head." Two days before admission the abdomen suddenly began to swell, and this symptom had rapidly increased.

Examination on admission.—There is marked mental confusion, the patient being unable to answer any questions intelligently. The temperature is subnormal, the pulse 132°, small, and very compressible. The abdomen is greatly and uniformly distended, tense and tympanitic, and extremely sensitive on palpation. Examination per rectum and vaginam gives negative results. The heart's apex is displaced upward, and is felt in the third interspace. There is evidence of a limited area of consolidation, with softening, at the apex of the right lung. There is no physical evidence of other visceral disease. The urine is free from albumen, sugar, and casts. The case was believed to be one of general peritonitis of doubtful origin.

March 13th.—The patient's condition is worse; only eight ounces of urine have been passed during the past thirty-six hours. The abdomen is greatly distended and tympanitic. There has been no movement of the bowels since admission; temperature, 101.2°F.; pulse, 134, small and weak. Catheterization shows the presence of only a small quantity of urine in the bladder; that withdrawn is free from albumen and glucose, but contains very numerous hyaline casts. An enema was followed by a small movement, consisting, presumably, of the contents of the lower bowel. The patient's temperature continued to rise, reaching 104.4°F.; the pulse to increase in frequency; the abdominal symptoms remained unchanged, and death occurred on the 14th, four days after admission.

Necropsy.—The pathological changes were confined to the lungs and intestines. The following notes are taken from Dr. Ferguson's report: The right lung is infiltrated with miliary tubercles; an occasional caseous mass is found, and at the apex three small cavities, each the size of a bean, are present. There is also a small focus of softening in the upper portion of the middle lobe. The left lung contains numerous miliary tubercles.

The peritoneum is normal.

The large bowel is enormously distended throughout and is filled with fluid fecal matter; the distention is especially great in the cæcum and the ascending and transverse sections of the colon. Just above the cæcum the gut laid open measures ten inches in width. The mucous membrane of the lower portion of the ileum is intensely congested. There are numerous ulcers in the cæcum and ascending colon, oval in shape, measuring from one inch to one and a half inch in length and half an inch in breadth. The long axes of these ulcers are transverse to the axis of the gut. The muscular coat is involved in many of the ulcers, but nowhere has perforation occurred. An ulcer, similar to those described above, is found in the lower portion of the descending colon. The total number of ulcers is thirteen. The intestinal canal throughout is absolutely free from obstruction of any kind.

Remarks.—The diagnosis in the above case was necessarily based upon the physical signs described, as no history of the patient's illness was obtainable until immediately previous to death. The extreme and symmetrical distention of the abdomen, the tympanites with marked sensitiveness on palpation, the gradual increase in these symptoms, and the pyrexia, combined to form a clinical picture of an acute general peritonitis. Its origin and nature admitted of varied opinions. My colleague, Dr. McBurney, kindly examined the case at my request, and concurred in the diagnosis of general peritonitis. The necropsy demonstrated the incorrectness of this diagnosis, and at the same time the dependence of the symptoms, and physical signs described, upon a paralysis of the large intestine, the result of tubercular ulceration. The not infrequent occurrence of acute paralysis of the intestine after surgical operations on the abdomen is at present well recognized; a similar pathological condition of the bowel, the result of deep ulceration, in typhoid fever, has also been described. The present case is of interest, in the extreme degree of the paralysis (in itself an efficient cause of obstruction) and abdominal distention, in its causation, and finally in its clinical simulation of acute general peritonitis.

CEREBRAL SYMPTOMS IN THE PNEUMONIA OF CHILDREN.[1]

By L. EMMETT HOLT, A.M., M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK INFANT ASYLUM.

Two points about pneumonia are brought out very prominently in almost every text-book devoted to diseases of children. The first is that disturbances of the central nervous system are much more likely to be met with in young children than among adults; the second, that these are almost invariably associated with disease of the apex of the lung. My own experience abundantly confirms that of others regarding the first point. Since the second one, however, has been denied by an eminent authority,[2] I have gone over my own clinical records with reference to nervous symptoms, and submit the results in this paper for your consideration.

There existed for analysis one hundred and seventy-three cases, which may be briefly characterized as follows: Seventy-three were lobar pneumonia,[3] with two deaths; and one hundred, broncho-pneumonia, with a mortality of thirty-four. The sexes in broncho-pneumonia were nearly equal; while in lobar pneumonia the males predominated, forty-three to thirty. As to age, one hundred twenty-three patients were two years of age or under, and only thirteen were over five years of age.

Thirty-four cases, or twenty per cent. of the whole number, presented decided cerebral symptoms. I have divided these into three groups: Those attended by convulsions, of which there were fourteen; those where delirium was the principal symptom, twelve in number; and the third class, where neither convulsions nor delirium existed, but other symptoms decidedly cerebral in type—of these there were eight cases.

The convulsions of pneumonia differ in no respect from those seen in meningitis or other acute disease. In half of the cases they were a symptom of invasion, in the other half they came on toward the close of the disease. Only one case presented both early and late convulsions. In almost all instances the movements were general, and in by far the larger number they were repeated more than once. Initial convulsions were succeeded by drowsiness or semi-stupor, sometimes a light delirium or great irritability; there being nothing usually in the symptoms to indicate pulmonary disease during the first twenty-four, or even forty-eight hours.

Delirium was rarely seen for the first two or three days. It was most marked at the height of the disease—fourth to the seventh day—and, if intense, generally lasted until the crisis. It varied much in intensity—in the milder forms amounting only to incoherent rambling during sleep; in the severer forms being sometimes low and muttering, like that in typhoid, but more commonly wild and excited, like that of cerebro-spinal meningitis. In this condition some of the patients could with great difficulty be kept in bed. In addition to delirium, they had dilated or contracted pupils, involuntary passages of urine and fæces, boring of the head into the pillow, retracted abdomen, sordes on the lips and teeth, muscular twitchings, tremor of the tongue on protrusion, irregular pulse; in short, almost every symptom of cerebro-spinal meningitis.

Other patients had persistent drowsiness or semi-stupor, these occasionally alternating with periods of great irritability or excitement, sometimes terminating in convulsions, simulating very closely tubercular meningitis.

Vomiting I have not included in my analysis among the cerebral symptoms, as it is almost a constant symptom in the invasion of pneumonia. Headache was frequent in children old enough to describe their sensations, but as the great majority of my cases were not, I have not included this symptom.

Continued irregular respiration I have not seen, although this has been mentioned by Rilliet and Barthez. Nor have I met with the decubitus *en chien de fusil* or gun-hammer position, although cases have been reported by Starr, of Philadelphia, Jenner, of Toronto, and others.

The two classes of symptoms made by the French writers, viz., eclamptic or convulsive, and the meningeal or delirious, serve very well for purposes of description, but almost every combination of the symptoms enumerated has been met with.

Diagnosis.—How are these cases to be distinguished from meningitis? is the practical question of most importance in this discussion. First, only by careful and repeated examinations of the chest. And just here I wish to say that there is no sin of omission of which the general practitioner in his care of children is more often guilty than this. It is something which is often beset with difficulties, no doubt, yet there are very few cases in which, with patience and tact, as satisfactory examination cannot be made of a child's chest as an adult's. I have made it a rule, in cases of acute illness, to make a physical examination of the chest every day until the diagnosis was clear beyond the shadow of a doubt; and I have been surprised over and over again to find in how many cases, obscure and often indefinite symptoms have been found to depend upon pneumonia. Its great frequency in early life lays upon us always the necessity of excluding it, before accepting any other explanation of a persistent high temperature in a child.

The difficulties in the case are much increased by the late appearance of positive physical signs, as in central pneumonia, although the time when they are manifest depends quite as much upon the physician's acuteness of observation as upon the state of the lungs. In my own experience I have found that the number of cases with late physical signs gradually grows smaller year by year.

Cough is usually present, but it is wanting in the first two or three days in a sufficient number of cases to make it of little value in the doubtful, obscure ones.

Activity of the alæ nasi may be seen in many other conditions, but it is rarely absent in pneumonia.

Alteration of the pulse-respiration ratio is more important than any other single symptom. Accelerated respiration, out of proportion to pulse and temperature, should always lead us to suspect the lungs, whatever other symptoms are present. Irregular respiration, especially of the Cheyne-Stokes type, is almost never seen in pneumonia.

---

[1] Read before the New York County Medical Society, March 26, 1888.

[2] Eustace Smith: Clinical Studies of Diseases of Children, 1887.

[3] I recognize the fact that many cases are *clinically* lobar which do not give at autopsy the lesions of croupous pneumonia.

The slow, irregular or intermittent pulse in meningitis does not occur in pneumonia. Irregularities and intermissions in a rapid pulse are quite common but are of no significance.

It is very rare for the temperature in meningitis, either tubercular or cerebro-spinal, to remain so high as we commonly find it in pneumonia. In fact, Thomas (" Gerhardt's Handbuch ") asserts that a persistent high temperature almost certainly excludes meningitis. The loss of knee-jerk is the rule in meningitis (Hughlings-Jackson and Angel Money). I am not aware that it has been recorded to be absent in pneumonia and can see no reason why it should not form as valuable a symptom for differential diagnosis of meningitis from pneumonia as it is said to be from typhoid fever.

Localized paralyses are not met with in pneumonia unless there be a complicating disease of the brain.

The cerebral symptoms of pneumonia are commonly less severe and not so continuous as those of meningitis, so that the progress of the case nearly always clears up the diagnosis by the rapid subsidence of the nervous symptoms at the crisis, although we may have been in some doubt up to this time.

Between broncho-pneumonia with cerebral symptoms and pulmonary tuberculosis with a few tubercles in the brain, I quite agree with Jürgensen that a diagnosis may be impossible.

Etiology.—Cerebral symptoms in pneumonia may depend upon complicating meningitis. This is asserted by almost all writers to be exceedingly rare. I have never seen it.

Steiner,[1] Bridge Lees,[2] and others have shown that they may arise from suppurative otitis media occurring as a complication, but this also must be rare, if we are to believe the writings upon the subject; perhaps not so uncommon, however, as the small number of recorded cases would indicate. I have met with but one instance.

Only one of the fourteen cases of convulsions was over two years of age, so that of one hundred and twenty-three cases two years of age and under, ten per cent. had convulsions. Delirium, on the contrary, was most common between the ages of four and eight years. Of the fifty cases over two years of age, thirty-three per cent. had delirium.

Temperature : Of thirty-three cases in which this was recorded there was hyperpyrexia in fourteen. In eight of these it reached 106° F., or over. Delirium and stupor were much more commonly associated with very high temperature than were convulsions.

In twelve cases the temperature was about the average for pneumonia (*i.e.*, 102° F. to 104.5° F.), and in six it was below the average.

Constitution : Fourteen children were reported in good health prior to the attack, seventeen were delicate, and one was markedly rachitic. Convulsions were more common in delicate children (nine out of fourteen cases). Of the twelve cases with delirium all but three were previously healthy.

Form of disease : Nineteen were cases of lobar pneumonia, fourteen were broncho-pneumonia, and one was not determined. Early convulsions were most often seen in the lobar form (seven of nine cases), while late convulsions in every instance but one, occurred in broncho-pneumonia. Delirium was seen much more often in the lobar form (nine of the twelve cases).

Location of the disease : The part of the lung affected has been a subject of special investigation, as I wished to ascertain whether these records supported the idea of the intimate association of cerebral symptoms with disease at the apex.[3]

There were thirty-eight cases of pure apex-pneumonia : Right, twenty-three ; left, fifteen. Of these cases seven, or eighteen per cent., had cerebral symptoms ; two, delirium ; three, convulsions ; two, other symptoms.

There were thirty-six cases of pure base pneumonia : Right, thirteen ; left, twenty-three. Of these cases four, or eleven per cent., had cerebral symptoms ; two, delirium ; one, convulsions ; one, other symptoms.

In seventy-three cases there was extensive disease : Both apices in two ; both bases in four, and in the remainder nearly the whole of one lung or large areas in both lungs were involved. Of these cases twenty, or twenty-seven per cent., had cerebral symptoms ; seven, delirium ; eight, convulsions ; five, other symptoms. In other words, in fifty-six per cent. of the thirty-four cases with cerebral symptoms the lesion was extensive. I have studied these cases with extensive disease a little further. In twenty-one of them the lesion involved either both apices, or the apex and some other part of the lung ; seven, or one-third, had cerebral symptoms. In thirty-six cases both bases, or one base and some other part, not the apex, were affected. Of these, twelve, or one-third, had cerebral symptoms ; a striking agreement with the apex cases.

These figures are not large enough, it is true, to establish the proportion of cases in which cerebral symptoms are met with when the disease is situated in the various parts of the lung, but they are large enough to show very clearly that no such predominance of apex cases exists as we have been led to believe. So far as they show anything, it is that the extent of disease is a far more important factor in producing nervous symptoms than its location.

The great predisposing factor here is to be found in the susceptibility of the nervous system in early life, which is one of the striking peculiarities of all the acute pathological processes of infancy and childhood. Sudden impressions by the abrupt development of symptoms, as in lobar pneumonia, are more likely to disturb the nervous centres than those coming on more slowly. Very extensive disease acts in a twofold manner, both by the nervous depression which it induces, and by the interference with hæmatosis, due to a large part of the lung being crippled, so that blood deficient in oxygen and overcharged with effete products is supplied to the brain and cord.

The fact that high temperature, from any cause whatever, when maintained for any considerable time, will produce marked disturbance in the functions of the brain, is so well known that it scarcely needs to be mentioned here. When we have given the old explanation that these symptoms are due to the effect of the overheated blood upon the brain, we have said about all that is positively known upon the subject.

Prognosis.—The general mortality of the cases here analyzed was twenty-two per cent. ; of the thirty-four cerebral cases ten, or thirty per cent., proved fatal. Of eight cases in which convulsions occurred at the onset of the disease only one died. The others were not specially severe. Every case of late convulsions died within twenty-four hours. One of these cases also had convulsions at the beginning of the pneumonia. Only one of the twelve cases with delirium succumbed. These cases, however, included some of the most severe ones in the series. We may conclude, then, that, excepting late convulsions, the occurrence of cerebral symptoms in pneumonia does not very much increase the danger of the disease.

It will be of interest to compare these cases with those of pneumonia in older children.

In the reports of the Pendlebury Hospital, Manchester, for the years 1881 to 1886, there are tabulated two hundred and thirty-four cases of lobar or croupous pneumonia. The hospital admits children from two to fourteen years of age. The ages of the cases of pneumonia were as follows : Under five years, 67 ; five to ten years, 121 ; ten to fourteen years, 46—total, 234. Only three cases are mentioned as proving fatal ; two of these had marked delirium. One hundred and forty-two were males, ninety-one females.

[2] Practitioner, August, 1886.

[3] This term will be used synonymously with " upper lobe " in the subsequent discussion. I have found it impossible to draw the line of distinction between them in making up my statistics, nor has it been done by most writers.

Table II., which I have constructed from these reports, shows the proportion of base and apex cases, the number in which there was extensive disease upon one side, or in which both lungs were affected, together with the number of cases with delirium and convulsions when the disease was situated in the different parts of the lung.

For convenience of comparison I have placed alongside of it, in tabular form, the one hundred and seventy-three cases which have been discussed in the earlier part of this paper (see Table I.).

TABLE I.—173 *Cases of Pneumonia* (123 *under two years of age*).

Location	Apex, 38 R., 23 L., 15	Base, 36 R., 13 L., 23	Extensive disease, 73. (Both apices, 2; both bases, 4.)	Whole number, 173
Delirium	2	2	7	12
Convulsions	3	1	8	14
Other cerebral symptoms	2	1	5	8
Total with cerebral symptoms	7	4	20	34
Percentage	1	11	27	20

TABLE II.—234 *Cases in Older Children* (121 *between five and ten years of age*).

Location	Apex, 61 R., 47 L., 14	Base, 84 R., 29 L., 55	Extensive disease, 89. (Both apices, 4; both bases, 20.)	Whole number, 234
Delirium	14	13	28	55
Convulsions	.	3	2	5
Total with cerebral symptoms	14	16	30	60
Percentage	23	19	33	25

In all the five cases of convulsions they occurred at the onset of the disease; only one was a severe case and none were fatal.

In looking at these two tables we are struck with the fact that the right apex and the left base are the parts of the lung attacked by preference, these two being involved with nearly equal frequency. The proportion of cases having cerebral symptoms is slightly larger (twenty-five per cent. to twenty) among the older children, a fact which rather surprised me.

We see, however, that with the exception of all the percentages being slightly larger in Table II., there is a striking agreement in the two series of cases. Thus, in both tables the proportion of cerebral cases in those of disease at the apex falls a little below the general proportion. The proportion among apex cases is considerably larger than among the base cases, but it is far below that among the cases with extensive disease.

We may then safely draw the following deductions:

1. Cerebral symptoms in the pneumonia of children are very common.

2. Convulsions belong almost without exception to infancy, being rarely met with after two years. Occurring at the onset, they belong essentially to lobar pneumonia; they do not indicate a bad prognosis, nor even, in most cases, a severe attack. When late convulsions come on, death within twenty-four hours may confidently be predicted.

3. Delirium comes oftenest between the ages of five and eight, usually in conjunction with extensive disease and high temperature. These cases, although severe, with but few exceptions recover.

4. There is no such intimate association between cerebral symptoms and apex disease as has been frequently stated. Such symptoms occur in only about one-fifth of the apex cases.

5. Nervous symptoms occur much more frequently (one-third of the cases) when the disease is extensive and the temperature very high.

It was not my purpose to enter into the subject of the treatment of these symptoms in pneumonia, as I have nothing new to contribute. I wish to emphasize two points which my experience has taught me. The first is that in hyperpyrexia the cold pack is safe, and the most efficient means to reduce the temperature and thus abate the brain-symptoms dependent upon it. The second is the use of antipyrine, not so much for reducing very high temperature—for I think the cold packs are safer than very large doses, and altogether more satisfactory—but to allay restlessness, quiet delirium and cough, and promote sleep. For this purpose, doses of two or three grains are sufficient in an infant of from six to nine months, and double the dose at eighteen months or two years. The dose may be repeated every six or eight hours.

Clinical Department.

A PIN LODGED IN THE PHARYNX.

DR. GEORGE WHITE, of Chicago, writes: "As an illustration of how long the human pharynx will tolerate a severe and constant irritant, allow me to place on record what seems to me to be an extremely interesting case. On February 1st I was hastily called to remove a pin from a child's throat. The history of the case was simple. Sometime during the month of June, 1887, the little girl (then about eighteen months old) put a pin into her mouth, and in a little while it slipped over the tongue, and the customary symptoms followed. The family doctor was summoned, but the pharyngeal walls were so œdematous that he was unable to locate the pin. A second physician was called and he, too, failed. As week after week went by the baby's condition grew no worse, but there were irregular seasons of coughing till I took up the case. At first I would not believe the history, but every statement was corroborated. To inspect the throat, I passed a finger of my left hand over the tongue, and then pressure on the middle and posterior parts of the tongue caused some nausea. This sensation being always accompanied by the involuntary elevation of the uvula and edge of the soft palate, I could plainly see the obstruction lying crossways in the throat and immediately behind the tonsils. I grasped the pin with a pair of bullet-forceps, and, forcing one end of it against the right side of the throat till I could see the end that had been fixed behind the left tonsil, it was a very short time till the child was free from its danger. The pin was brass, and presented no signs of corrosion. There were no indications of the least particle of pus, and the bleeding that followed the extraction was very slight. Up to the present time my little patient has progressed favorably."

THE TREATMENT OF SEPTIC DYSPEPSIA.

DR. H. F. GILLETTE, of Cuba, N. Y., writes: "I wish to call attention to the treatment of that form of dyspepsia characterized by acidity and fermentation—the condition known as septic dyspepsia. For over five years I have frequently prescribed the following in such cases:

℞. Salicylic acid........................gr. j.
Pepsin..........................gr. iij.
M. To be given at one dose, half-hour before eating.

"The combination acts as a disinfectant, and destroys those micro-organisms which act, like the yeast-plant, in starting the fermentative process in the food taken into the stomach. The action of the yellow oxide of mercury, recommended by Dr. Rose, is very similar, and the drug may be preferred in certain states of the system. I have found it convenient to give the prescription in form of tablets."

"LA ENCICLOPEDIA," a monthly journal published in Havana, appeared for the last time in December, 1887, at the end of its third year.

Progress of Medical Science.

PNEUMOPARESIS.—In a recent paper read before the Medical Society of London, Dr. B. W. Richardson proposes a new term for simple respiratory failure, viz., pneumoparesis. *The Lancet* says apropos of this subject: The question is whether a condition of disease of the lungs exists which warrants the name and calls for it. In support of the affirmative of this view Dr. Richardson's exposition runs as follows: Under the general expression "pneumonia" there occur instances in which there is no fever, no acute pain, no rusty expectoration, no preceding rigor—no indication, in short, of symptoms of febrile excitement. In place of these symptoms, however, there are certain other symptoms which of themselves are special and pathognomonic. The sufferers are persons possessing peculiar heredities. They are of phthisical tendency, they are of emotional nature, and are easily susceptible to what are called nervous shocks and exhaustions. Following upon such shocks or exhaustions, physical or mental, they suddenly become prostrate, with emotional or hysterical perturbation. They have cough, without either pain, difficulty of breathing, or much expectoration; and they exhibit strikingly, on the cutaneous surfaces of the neck and face, the red blush which the older writers called "erythema fugax." The pulse is variable and a little quickened, and the breathing is changed in a similar manner, but neither is remarkably modified. The mind, as a diagnostic surface, presents its own special features. Mingled with some emotional excitement there is a fixed belief in the mind of the patients that they shall not recover, but the belief, at the same time, is combined with the most perfect resignation to death. These are the general symptoms. The local, as soon as they are developed, are dry crepitation, strictly pneumonic in character, commencing at the base of the lung posteriorly, as a rule, extending quickly to the other lung, soon becoming moist, and steadily progressing through the pulmonary structures. In spite of all treatment the mischiefs indicated by the crepitation proceed until death takes place by asphyxia, the mind remaining clear until coma sets in, and the digestive and other functions remaining as little affected as the mind until the final catastrophe. Now that the class of symptoms have been defined, there is little difficulty in recognizing them. They are known, if not familiarly known, to all who have had a long acquaintance with the practical history of thoracic disease. They have no doubt been connected with other conditions of disease, but they possess, when once correctly pointed out, their own distinctive qualities; they are attended with failure of the respiratory power, and they constitute truly pneumoparesis, whatever may be their cause. But Dr. Richardson, after thus defining pneumoparesis, goes to its cause. He has seen in experiments the same physical symptoms produced synthetically in the lower animals, by an induced paresis of the nervous supply of the lungs. Hence he infers that the disease is of nervous origin. There are subjects in whom the nervous stimulus to the vascular systems of the lungs, nutritive and respiratory, is at all times defective. These, under the influence of depressing causes or of nervous shock, exposure to cold, privation, accident, fear, grief, or even extreme excitement, feel depression in, so to speak, the most defective part, and thereupon the vascular tone of this pneumonic area is reduced. On that the resistance of the minute circulation is lessened, and the physical changes leading to the confirmed organic lesions commence and progress as related above. It is a fine point whether the change commences in the nutritive vessels of the lung or in the respiratory, but on the whole the author of the theory thinks it begins in the nutritional circulatory channels, the respiratory circulation following in train and yielding the evidence from physical signs of the organic disturbance. This point is novel, and is as applicable to other forms of lung disease as to that under special notice. By a further extension of his theory, Dr. Richardson gives pneumoparesis another bearing. It is, he argues, the natural mode of death in the aged, the method of final sleep, the true euthanasia. In the course of the process of senile decay the nervous supply of the pulmonary vascular systems becomes gradually enfeebled. At last, under the influence of some depressing cause, the failure is complete, so-called congestion of the lungs or congestive bronchitis ensues, and under the withdrawal of the respiratory function the anæsthetic state is induced which ends in death. Those who die from pneumoparesis, therefore, in old age, have lived their allotted term; those who die from it in earlier life have been born to a premature death. To the interest attaching to this curious and practical topic there is, we regret to say, one painful part. For pneumoparesis there is, according to our present knowledge, no cure.

TREATMENT OF WINTER ECZEMA.—A correspondent from Brooklyn calls our attention to a lotion recommended by Dr. Squibb, in the *Ephemeris* for March, 1882, from the use of which he has found great relief. The following is the formula for this lotion: Tannic acid, 40 grains (2.6); glycerine and alcohol, of each 4 drachms (15.0); water, enough to make 4 ounces (120.0). This is to be applied to the itching surface by means of a small sponge or rag, morning and evening. The solution does not keep indefinitely, and should therefore be renewed occasionally. The writer also states that a friend of his has found the same lotion an excellent palliative in chronic eczema, keeping the irritation within the bounds of endurance. Another correspondent, from Conway, N. H., writes that he has had more real satisfaction and solid comfort from the use of an iron shoe-horn than from any other remedy which he has tried in winter eczema. His trouble is located chiefly at the angle of the scapula, and the iron "goes to the right spot."

A DOSIMETRIC PRESCRIPTION.—Dr. Semeleder, of Mexico, writes: "A man, aged forty-five years, suffering from pneumonia, was treated by the dosimetric method, the following being one of his prescriptions, the figures representing granules to be taken at a dose. Bromocamphor, 8; quinine hydrobromate, 4; arbutine, 1; strychnine hypophosphate, 1; aconitine, 1; veratrine, 1; digitaline, 1; sodium benzoate, 1; iodoform, 1; helenine, 1; musk, 1. These were to be taken once in every two hours, that is to say, a new medicine every ten minutes. In addition, two granules of quassine were given every time the patient took any nourishment. He took an average of three hundred granules a day, or three thousand in the course of ten days, when he died. The cost of medication for this period was $45.00."

GRAVITY AS AN EXPECTORANT.—It is claimed in *The Polyclinic* that in cases of pneumonia where there is great embarrassment of breathing from accumulation of secretion in the bronchial tubes, great benefit may often be derived by inverting the patient and having him cough violently while in this position. It is easily accomplished by a strong assistant standing on the patient's bed, seizing the sick man's ankles, turning him with his face downward, and then lifting his feet four or five feet above the level of the mattress. If the patient, with his face over the edge of the bed and his legs thus held aloft, will cough vigorously two or three times, he will get rid of much expectoration that exhaustive efforts at coughing failed to dislodge when not thus aided by gravity. Life has been saved by repeated performances of this manœuvre in pneumonia accompanied with great cyanosis, due to inundation of the bronchial tubes with mucous secretion.

DR. A. BERTHERAND, founder and editor-in-chief of the *Gazette Médicale de l'Algérie*, died in Paris in December of last year. He was born in Bazeilles, Ardennes, in 1815, and was therefore nearly seventy-three years of age at the time of his death.

New York, April 7, 1888.

DIPHTHERIA IN POULTRY, AND ITS RELATION TO THE DISEASE IN MAN.

IT has been noted by several writers that the diphtheritic process, as it occurs in the human subject, resembles in many respects that occurring in barn-yard fowls, and it has even been suggested that the human disease might be originated or spread through the agency of chickens or other poultry.

In the *Bulletin Médical* of January 22, 1888, Dr. Paulinis publishes an interesting report of an epidemic of diphtheria, occurring in one of the Grecian isles, which lends considerable weight to the arguments in support of this theory. The epidemic began in the summer of 1884, in Skiatos, a small island having a population of about four thousand souls. For over thirty years no case of diphtheria had been seen on the island, according to the testimony of a Dr. Bild, who had practised there during that time. In the early part of June Dr. Paulinis was called to see a child aged twelve years, suffering from sore throat, and found her tonsils and pharynx covered with false membrane. This child died, and seven other cases occurred in the immediate neighborhood, five of them terminating fatally. The epidemic soon spread through the entire community, over one hundred being attacked, and thirty-six dying during five months.

An examination was made to discover, if possible, the source of the disease, and it was found that a flock of turkeys had been received some three weeks before from Salonica. Two of the turkeys were sick on their arrival, and each of the others was attacked in succession. Dr. Paulinis found two of them still sick, and inspection showed patches of pseudo-membrane on the mucous membrane of the vault of the palate and of the pharynx. On detaching strips of the exudation by the forceps the mucous membrane beneath was seen to bleed slightly. The glands of the neck were swollen, and in one of the fowls the diphtheritic process had extended to the larynx, as was shown by the hoarseness of the cry and evident dyspnœa. One of the turkeys, which had recovered from the throat affection, suffered from paralysis of the legs, being unable to walk. The garden where the turkeys were was at the northern extremity of the town, and the first children attacked were in the immediate neighborhood. There had been no immediate contact between the fowls and the children, nor between the first child attacked and the others, but there was a north wind blowing the greater part of the time, and the author believed that it was in this way that the disease was spread. He concluded, from this experience, that the diphtheria of the ordinary barn-yard fowls was similar in its course and symptoms to the disease occurring in man, and that it could be carried from the one to the other, sometimes through the medium of the air.

The question of the intercommunicability of human and animal diseases is an interesting one from many points of view, and this account of an epidemic in a community hitherto exempt from diphtheria is an important contribution to the literature of the subject, although it must be confessed the recital of it is by no means entirely satisfactory, as far as the exclusion of various sources of error is concerned.

THE ACTION OF SPARTEINE.

ALTHOUGH sparteine has been known for many years, it is only within a comparatively recent period that its valuable properties as a true heart tonic have been recognized and carefully studied. Dr. J. Pawinski, of Warsaw, has recently made a somewhat extensive series of experiments with the drug (*Gazeta Lekarska*, Nos. 1 and 3, 1888), and comes to certain conclusions which are of interest, as they differ in some respects from those of other writers.

1. Sparteine acts without doubt on the heart and great vessels.

2. In small doses, of one-fourth to one-half grain, three times a day, it increases the strength of the heart's action, reduces the number of pulsations, and raises the blood-pressure. In large doses, one and a half to two grains, every two hours, it exerts a paralyzing influence on the heart, diminishing the frequency and force of the beats, as evidenced by a slow, feeble, and often intermittent pulse.

3. The best therapeutic effect is obtained with small doses.

4. Small doses stimulate, while large ones paralyze, the pneumo-gastric nerve.

5. The stimulant action of sparteine upon the heart cannot be regarded as very considerable, and in this respect digitalis is superior.

6. In small and medium doses sparteine seems to exert a stimulant effect upon the vaso-motor centre in the medulla, in consequence of which the vessels become contracted.

7. The action of sparteine is rapid, its effects being observed within half or three-quarters of an hour, and continuing for four or five hours.

8. The best effects of the drug are seen when it is administered to delicate, nervous, or anæmic individuals.

9. In addition to its action upon the heart and vessels, sparteine also exerts a soothing influence upon the nervous system, being sometimes distinctly, though slightly, hypnotic.

10. The diuretic action of sparteine is not important. It is uncertain, occurring usually, however, in persons possessing considerable nervous susceptibility, whose cardiac muscle is not degenerated in consequence of morbid changes in that organ or elsewhere. The diuretic action of the drug, such as it is, seems to be due to the vascular changes produced by its influence.

11. Sparteine does not exert any cumulative effects,

and may therefore be administered for a considerable length of time without fear of any sudden injurious consequences.

12. Sparteine does not produce any digestive disturbances, and does not affect the appetite.

THE CONDITIONS OF LONGEVITY.

Professor Humphreys presents, in the *British Medical Journal* for March 10th, the final report of the collective investigation regarding aged persons. This report is based on the study of the family histories of eight hundred and twenty-four persons between the ages of eighty and one hundred years. The results of the investigation, as Professor Humphreys says, do not reveal anything very novel or startling, or give rise to fresh theories of longevity. They tend rather to dissipate certain ideas which are more or less current, though founded upon too limited observation, and to show that the maxims and laws which common-sense and sound reason would dictate hold good, and that, as a general rule, those persons live the longest who might be expected to do so. Thus, he adds:

"1. The prime requisite is the faculty of age in the blood by inheritance; in other words, that the body has been wound up, as it were, and sent into the world with the initial force necessary to carry on the living processes through a long period, that this is the case with every organ, and that the several organs are so adjusted to one another as to form a well-balanced whole. The various functions will then be equably and harmoniously performed, and there will, consequently, throughout life, be little cognizance of imperfection or ailment of any kind.

"2. The body is usually well developed, and though there are many exceptions to this, rather exceeds the average standard of height. It is capable of much endurance and of quick and complete restoration after fatigue, this latter faculty giving the habit of, and probably the desire for, early rising; and with it also is associated a good power of recovery from the disturbances caused by accident or disease. The cerebral or intellectual powers accord with the general good quality, and the whole nervous system is active and energetic without being irritable.

"3. Owing to the inherent good quality of the nutritive processes, those degenerative changes which, in advancing years, always more or less diminish the elasticity of the arterial coats and of other parts, are slow to occur, so that the pulse retains, in great measure, its softness, and the thorax its vital capacity, while stiffness of limb and general feebleness are late in their manifestation. The decadence of the teeth, which in the animal world generally sounds a death-knell, inasmuch as it deprives the body of the means of obtaining its subsistence, does not seem to augur much in the case of civilized man, to whom the teeth are less directly needed for his maintenance, while another cuticular appendage, the hair, seems to share, to some extent, the enduring quality of the rest of the system."

To the foregoing must be added ordinary opportunities for living well, and under sanitary conditions. Temperance in eating and drinking are essential, but especially in meat-eating and alcohol-drinking.

Professor Humphreys thinks that, on the whole, old age is an enjoyable period of life, when the body remains sound and the circumstances of life are comfortable.

Some of the more interesting physiological data are as follows:

The average height was a little over five feet seven inches; average weight, a little over eleven stone (154 lbs.).

The sight was good in 224 out of 267 cases; the hearing good in 188 out of 329. Out of 320 over one-half took a little, or a moderate amount of alcohol.

The average duration of sleep was seven and two-third hours. The pulse averaged about 70 to 74; respiration, 20 to 21 per minute. The arcus senilis was present in 172 out of 266 cases. The heart was affected in 42 cases; the lungs in 62; the brain in 25; the urinary organs in 119 cases.

A VICTIM OF "SPIRITISM."

Much comment has been aroused during the past week by the revelations concerning a distinguished lawyer of this city, who, in his old age, has allowed himself to be deceived by a spiritualistic adventuress. The credulity which the gentleman has shown is so amazing that legitimate doubts are expressed as to his mental soundness. We must quite agree with those who have expressed the view that the victim's mental powers are seriously impaired. The argument put forward in his favor that a distinguished jurist many years ago also became a convert to spiritualism, while his mental vigor, so far as legal matters were concerned, was not affected, hardly applies to-day. At that time spiritualism was a new thing, and its so-called phenomena not entirely understood by anyone. A man who now gives himself up so completely to a transparent trickery can hardly be considered a safe counsellor in serious matters.

News of the Week.

Death of Dr. Benjamin F. Dawson.—Dr. Benjamin Frederick Dawson died on Tuesday at his residence, 8 East Fifteenth Street, New York, of diabetes, from which he had been a sufferer for many years. He was forty-four years of age, and a graduate of the College of Physicians and Surgeons in the Class of '66. While a student of medicine he served as acting Assistant Surgeon in the United States Army during 1865. After graduation he practised in New York, paying especial attention to surgery, gynecology, and the diseases of children. He founded the *American Journal of Obstetrics* in 1868, and for six years continued as its editor. He contributed largely to this and other similar publications for many years. About four years ago he gave up the practice of his profession on account of ill-health. He had been for a number of years Assistant Surgeon of the Woman's Hospital, Attending Physician of the New York Foundling Asylum, and Professor of Gynecology in the New York Post-graduate Medical School. He was also a member of the New York Obstetric Society, and many other medical associations. He leaves a widow and two little children, besides three sisters, all of whom are married. The funeral occurred on Friday, at Calvary Church.

Contributions to Homœopathy.—Within a year or two the homœopaths of this city have secured, it is said, considerably over one hundred thousand dollars for their college and hospital here. By a fair, which is now going on, it is expected that $100,000 will be realized.

THE COMMENCEMENT OF THE COLLEGE OF PHARMACY OF THE CITY OF NEW YORK took place at Steinway Hall, Wednesday evening, March 28, 1888.

DR. SKODA, medical referee for Bohemia, and brother of the great J. von Skoda, died recently at the age of eighty-eight years.

UREA CENTRE.—In the animal economy centralization is carried to its most extreme degree. It is certain, from Brown-Séquard's experiments, that there exists a centre of irritation which can suspend the chemistry of the body, making the blood in the veins flow red and reducing the temperature of the body. MM. Sée and Gley, experimenting on dogs with a view to producing glycosuria, caused azoturia by irritating the central end of the divided right vagus with a mixture of glycerine, water, and lycopodium injected into that part of the nerve after section. —*The Lancet.*

SMALL-POX has increased so rapidly in San Francisco as to occasion alarm.

HISTORIC STONES.—This is the name suggested by *The Lancet* for the renal calculi which killed both Emperor William and his vanquished antagonist, Napoleon III.

OUR GERMAN BRETHREN JEST.—At a banquet given to Professor Kussmaul on the occasion of his leaving Strasburg for Heidelberg, we are told that Dr. Freund, professor of gynecology, after referring in humorous strain to the accident that had made Kussmaul a physician, viz., an accident to his foot which induced temporary lameness, and with it an interval of sage reflection, "evoked peals of laughter from his audience by hinting that, their names being identical in meaning, the Oribasius of the fourth century was no other than the Kussmaul of the nineteenth, but that the clinical teacher of Strasburg had greatly improved on his *alter ego*, the body physician to the Emperor Julian the Apostate." This was a highly effective sally, "Oribasius" being an exact equivalent in Latin for the German "Kussmaul" (literally, "kiss-mouth").

THE BRITISH MEDICAL ASSOCIATION, though numbering over 12,000 members, has recently got a decided set-back from political authorities (*Hosp. Gazette*). The Association sent a communication to the Government giving the unanimous opinion of 1,200 army medical officers on the question of relative rank. To this the Government has said that the opinions appear to have been obtained in a manner altogether in contravention of military rules. Army medical officers, like others, had a proper channel through which to be heard, and it was not prepared to accept a civilian circular from any association on their behalf.

AN ELECTRO-THERAPEUTICAL SOCIETY has been organized in Baltimore. New York had a Society of Electrology and Neurology at one time, but it died a natural death. We wish a better fate for the Baltimore organization.

A COMMITTEE OF THE TRUSTEES of the Johns Hopkins Hospital, at Baltimore, visited Boston and New York this week and spent much time in inspecting the hospitals of those cities, from a managerial standpoint.

DR. BRAMANN, the surgeon who successfully performed tracheotomy on the present Emperor of Germany, is only thirty-five years of age. He has been gazetted in Berlin as the recipient of the Commander's Cross of the Hohenzollern House Order as a reward for his services.

THE FRENCH CONGRESS OF SURGERY.—The third annual congress of French surgeons was held during the week ending March 17th, at Paris. M. Verneuil presided, and in his opening address replied to the recent attack upon French surgery made by Billroth. M. Verneuil said that the tendency of French surgery was conservative, and it was certainly more enlightened than that which consisted in the daring ablation of every possible organ, and which placed operative interference in the first rank among therapeutic agents. While reserving the knife for necessary cases, French surgery attempts to utilize as far as possible all the help that can be obtained from hygiene and general therapeutics. "If," said M. Verneuil, in conclusion, "the fame of the surgeon who acts upon these principles is not trumpeted to the world, as would be the case were he to cut out a lung, or to tie the basilar artery, he may console himself by the thought of the number of cases in which he has secured health and saved life without making a fuss over it." The first communication was made by M. Ollier, of Lyons, upon two cases of resection of the wrist, with recovery of movement. The improvement advocated by M. Ollier consists in the conservation of the tendons of the muscles acting on the wrist-joint itself. Not only did the patients recover, with movement in the fingers, but also with a considerable degree of flexibility of the hand upon the arm, one of the patients, a young woman, even being able to play the piano. M. Demons related two cases in which he had practised partial extirpation of the larynx for cancer. In one case the disease recurred nine months later. The other patient, operated on ten months since, is still well. MM. Dupont and Mollière spoke upon the same question, the latter praising Trendelenburg's cannula. A long discussion took place upon the proper line of conduct in penetrating wounds of the visceral cavities. M. Chauvel said that the opinion of French surgeons was divided as regards the necessity for immediate laparotomy. There are the "abstentionists," comprising MM. Tillaux and Verneuil; the "moderate interventionists," such as MM. Reclus, Trélat, Bouilly, and Le Fort, who operate at the first signs of peritonitis or serous effusion; and, lastly, those who, following Hamilton and MacCormac, always perform laparotomy as an exploratory measure. M. Chauvel said that he belonged to this school, and considered that every wound of the abdomen by firearms required enlargement and exploration of the subjacent parts. Wounds of this kind are extremely serious, if not always mortal, when there is no surgical intervention; and, although he did not rely much upon the statistics he had collected, he thought they went to show that non-intervention was a mistake. In forty-one cases of laparotomy for gunshot wounds of the abdomen, the proportion of recoveries was twenty-nine per cent. The operation was the more successful the earlier it was practised. Within the first twelve hours there were forty per cent. of recoveries; within twenty-four hours thirty per cent. After twenty-four hours a fatal result had been constant.

Dry Mouth is the title of a paper recently read by Dr. W. B. Hadden before the London Clinical Society. The affection occurs in old people, and was benefited by jaborandi.

American Sanitaria.—The *Lancet* has an article upon this subject, dealing briefly with Colorado, California, Florida, and Minnesota. The *Therapeutic Gazette* recently published an article claiming especial merits for a new region in Colorado, viz., Glenwood Springs.

The Death of Dr. Emil Bessels is announced. Dr. Bessels graduated in medicine at Heidelberg, but he practised his profession for only a short time. He turned his attention to the natural sciences, and was prominently known as a member of the Polaris expedition. Dr. Bessels was only forty-one years old at the time of his death.

Brief Inhalations of Carbonic Acid Gas are said by Dr. E. Weil to relieve cough and dyspnœa.

The Action of Drugs at a Distance.—As might have been expected, the commission appointed to test the claims of M. Luys regarding the action of drugs at a distance upon hypnotized persons has reported that carefully conducted experiments fail entirely to produce the phenomena.

The Medical Society of the State of Pennsylvania holds its thirty-ninth annual meeting at Philadelphia on June 5th, 6th, and 7th. The following addresses will be given: Address on Practice of Medicine: Dr. E. R. Mayer, of Wilkesbarre; address on Surgery: Dr. James McCann, of Pittsburg; address on Obstetrics: Dr. Theophilus Parvin, of Philadelphia; address on Mental Disorders: Dr. Horatio C. Wood, of Philadelphia; address on Otology: Dr. B. A. Randall, of Philadelphia; address on Hygiene: Dr. Traill Green, of Easton.

Association of American Medical Editors.—The next meeting of the Association of American Medical Editors will be held in Cincinnati, Monday evening, May 7th. After the address of the President, Dr. William Porter, of St. Louis, the Association will consider a plan of organization reported by a committee, of which Dr. McMurtry, of Danville, Ky., is chairman. Officers for the ensuing year will be elected, and the Association will then discuss the following questions: 1. Is the multiplicity of medical journals an advantage to the profession? 2. How far do medical journals distributed by drug houses and manufacturers interfere with regular medical journalism?

Antipyrin, when given with ergot, is said by Professor Chouppe to produce painless uterine contractions, and therefore to be a most useful combination after parturition or in dysmenorrhœa.

Somniferin is the suggestive name given to a new morphine-ether which was first discovered by E. Bombelon, and is claimed by him to be superior to morphine. Smaller quantities can be used with similar results, headache never follows its use, constipation is seldom observed, and the heart is not affected. The drug is a transparent, colorless crystal, and is easily prepared. Bombelon has also discovered several new alkaloids, which he has produced from the same source. Morphine-eserine, which contracts the pupil without pain; also chinintropine and morphinotropine. According to Bombelon, a vast number of new bodies can be produced from the same source by means of various alkaloids; they retain both the chemical and physiological actions of both alkaloids, or, in some cases, contain new properties. Physiological experiments with these bodies are being actively carried on.—*Der Pharmaceut*, December, 1887.

Medical College Commencement.—The Louisville Medical College graduated a class of ninety-five at its recent annual commencement.

Politics and the Hospitals.—The *Chicago Medical Journal and Examiner* says that the value of the Cook County Hospital, as a means of clinical teaching, has been very much crippled in the past by the fact that men not qualified to teach have been able to buy positions on the staff. Our contemporary questions whether the "Reform Board" has brought about reforms in this respect, although it has placed some good men on the staff. It cannot be expected that public charities will attain their highest efficiency so long as they are managed by politicians. The deplorable state into which the charitable institutions of Indiana have fallen is the result of the "spoils system" in politics, and not until they are placed in the hands of non-partisan boards can it be expected that they will be managed honestly and efficiently.—*Indiana Med. Journal.*

The Microbe of Yellow Fever, as described and cultivated, attenuated and inoculated by Dr. Domingos Freire, of Rio Janeiro, has gone the way of many other specific germs. Dr. Gibier, who was sent from Paris to investigate the subject, denies utterly the existence of the germ claimed by Freire to be specific.

Another Medical Novelist.—Dr. Benjamin Ward Richardson has written a novel entitled "The Story of a Star: a Romance of the Second Century." The hero is Bar Cohab, the last of the great leaders of the Jewish people in the final struggle for national independence.

A Delayed Journal.—There are many excuses offered by overworked and underpaid medical editors for delay in the appearance of the journal. Sometimes the editor is sick, sometimes it is his baby; more often it is the calculated malignity of the printer and his imps. A Russian journal, *Medizinskoie Obosrenie*, offers a new excuse, viz., that three of its articles had been confiscated by the official censor. We had missed the *Obosrenie* greatly.

Italian Society of Hydrology and Climatology.—The Società Italiana d' Idrologia e Climatologia, which was founded last September at Pavia, when the Congress of the Italian Medical Association was in session, will hold its first meeting at Bologna next October.

Dr. J. Henry Fruitnight writes: "In the report of the discussion on Dr. Wood's paper before the Northwestern Society, I am quoted as saying the 'ingestion of nitrogenous,' whereas it should have been quoted 'ingestion of *non*-nitrogenous food'" (page 339).

Rochester Training School.—The sixth annual commencement of the Training School for Nurses, connected with the Rochester City Hospital, was held on the evening of Thursday, March 29, 1888. There were nine graduates.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 2, 1888.

George F. Shrady, M.D., President, in the Chair.

Dr. Andrew H. Smith exhibited a new combination of cocaine with saccharine, to which he had given the name,

SACCHARINATE OF COCAINE.

It had occurred to him that these two substances might be combined so as to form a useful salt, since saccharine is chemically an acid. The resulting salt was in the form of brilliant canary-colored crystals, which were very hygroscopic, and should, therefore, be kept in tightly closed bottles. A five per cent. solution of the saccharinate was about equal in strength to a four per cent. solution of the muriate, since there was proportionately a smaller quantity of the alkaloid in a given amount of the former salt.

Dr. Samuel Sexton referred to the case of a man who suffered from very severe vertigo after taking four drops of a four per cent. solution in his mouth for the relief of a toothache. He had often seen quite alarming vertigo following the instillation of cocaine in the ear in cases in which the drum-membrane was perforated.

Dr. Beverley Robinson had seen several instances of unpleasant symptoms caused by the application of strong solutions to the throat. These symptoms were faintness, vertigo, excessive pallor, and slight dyspnœa.

Dr. V. P. Gibney had occasionally met with patients who seemed to be insusceptible to the anæsthetic action of cocaine.

Dr. Cleveland had seen a case in which most alarming syncope followed the injection of a few drops of a ten per cent. solution into the gum, preparatory to a tooth-extraction.

Dr. Kinnicutt had exceptionally observed that the after-pain of an operation was much more severe than when no cocaine had been used.

Dr. A. H. Smith had observed this in one instance. He had removed a small tumor from the breast under cocaine-anæsthesia, and the woman complained afterward of very severe pain.

Dr. F. P. Kinnicutt reported a case (see p. 282) of

ACUTE INTUSSUSCEPTION.

Dr. L. M. Yale had seen one case which was believed to be intussusception, and which recovered. He referred to another which he had seen in hospital practice, in which the child died, and at the autopsy it was found that the invagination began at the jejunum, this part having passed entirely through the intestines, and appearing at the anus in the shape of a protruding loop.

Dr. Robinson reported a case seen by him with Dr. Cleveland. The patient was a child, aged one year, in whom the affection began with bloody discharges from the rectum. These discharges were later suddenly arrested, and a tumor appeared low down in the left side of the abdomen. The child was held with its head down, and a large quantity of water was injected into the bowel. While this was being done, some of the water came through the mouth. Three or four normal stools followed, and the child recovered.

Dr. Roosevelt related the case of a child which was supposed to be suffering from intussusception. It was taken suddenly with vomiting, swelling of the abdomen, and some blood in the stools, but there was no pain. Laparotomy was performed, but no intussusception was found. The child died, and at the autopsy it was found that there had been a band of fibrin causing strangulation of the transverse colon. The obstruction was entirely in the large intestine, and had been relieved spontaneously.

Dr. Abbe had had a case in a child who presented symptoms of obstruction, and in whom a tumor could very easily be felt. Injection of water resulted in a complete reduction of the obstruction. The child recovered, but died some time afterward from another intussusception. He believed that spontaneous reduction, when it occurred, was often due to the reversed action of the intestines, which was manifested by the stercoraceous vomiting.

Dr. A. H. Smith said that his impression was that many cases had been recorded of water escaping from the mouth after its injection into the rectum. He asked what significance Dr. Kinnicutt attached to the diminished secretion of urine.

Dr. Robinson asked whether the diagnosis of intussusception could be made without the presence of a tumor. He related a case of a boy who was suddenly seized with abdominal pain. When he saw the child in the evening there was severe pain in the abdomen, the legs were drawn up, and there was an elevation of temperature. The next day the boy was as well as usual. The mother said that the child was very liable to similar attacks, and her physician in another city had told her always to send for medical assistance at such times. Dr. Robinson asked whether this was a case of intussusception.

Dr. Kinnicutt said that, in connection with other symptoms of intussusception, the sudden appearance of a tumor rendered such a diagnosis much more positive. In intestinal obstruction from other causes the presence of a recognizable tumor was much less common. In reply to Dr. Smith's question, he said that the symptom of anuria was probably one of the phenomena of shock, and was not of particular significance in the diagnosis of the present case.

Dr. Kinnicutt then reported a case (see p. 382) of

PYLORIC STENOSIS FROM AN ULCER.

Dr. Cleveland remembered having seen this patient long ago, and at that time the diagnosis was chronic gastritis. The patient had always been very imprudent as regarded his diet, and had been in the habit of eating enormous quantities of candy.

Dr. Robinson asked what importance the reader of the paper attributed to the presence of an excess of acid secretion in the differential diagnosis of carcinoma and ulcer of the stomach.

Dr. Roosevelt asked whether the hyperacid condition of the stomach, so often seen in anæmic women, should be considered as a sign of any value, or as lending weight to the exclusion of carcinoma.

Dr. A. H. Smith thought that there was some danger of confusion in using the term acidity, without any qualification. All acid thrown off from the stomach was not hydrochloric by any means. He asked how it was possible to determine that the acid was hydrochloric without subjecting it to chemical tests.

Dr. Kinnicutt said that it was only possible by means of chemical tests to determine positively the presence of free hydrochloric acid.

In order to demonstrate the existence of gastric hypersecretion and hyperacidity, it was necessary to examine the contents of the stomach at varying intervals after the ingestion of food. The term hypersecretion was employed to denote the existence of free hydrochloric acid, independent of the presence of food in the stomach; hyperacidity, to an excess of this acid during digestion. In the former case the contents of the stomach should be examined six or seven hours after the ingestion of food; in the latter, about four hours after. If hydrochloric acid was present in any amount after the former interval, hypersecretion probably existed.

Hyperacidity could only be demonstrated by an estimation of the percentage amount of hydrochloric acid. He believed very positively that the constant presence of free hydrochloric acid during digestion excluded the existence of cancer, no matter how suggestive the other symptoms might be. Its absence might occur in other pathological conditions.

Dr. Kinnicutt then reported a third case (see p. 382) of

PARALYSIS OF THE LARGE INTESTINE FROM TUBERCULAR ULCERATION, SIMULATING ACUTE GENERAL PERITONITIS.

Dr. William H. Draper reported a case of

INTESTINAL OBSTRUCTION FROM IMPACTED GALL-STONE — LAPAROTOMY—DEATH.

I am indebted to Dr. Leroy M. Yale for the following details of the history of this case up to the time I saw the patient in consultation with him.

Miss M——, a maiden lady, aged fifty-one, always enjoyed fair health. The only facts in her antecedent history bearing possibly upon her final illness were as follows: In September, 1887, while in the country, she had what she considered a severe attack of indigestion, accompanied by severe pain in epigastrium, for which she was under medical care for three or four days. The attack does not appear to have been followed by jaundice. In November Dr. Yale was summoned, on account of a febrile attack, with more or less discomfort, but without severe pain, in the region of the liver. The fever was the principal symptom and yielded promptly to quinine. There was slight tenderness in the region of the gall-bladder for four or five days. An anodyne was needed for pain only once. There was no subsequent jaundice. On the evening of February 23d she had pain in the epigastrium, which she attributed to an indigestible muffin. In the morning her bowels moved, and she felt well enough to attend to her household duties and to out-door errands. Later in the day, Friday (the 24th), the pain recurred, and she began to take, of her own accord, small doses of calomel (gr. $\frac{1}{12}$), with bismuth. After taking six powders she took, on Saturday, a dose of oil, which was promptly rejected, but the bowels were moved by injection. The pain continued through Saturday, but Dr. Yale was not sent for until Sunday morning, the 26th. When Dr. Yale saw her she was without fever, and the pulse, which varied with the paroxysms of pain, averaged about 100. The paroxysms of pain, which were severe, varied in location, but were chiefly referred to the left of the mesian line and the left lumbar region. During the attacks of pain there was some tenderness over painful regions, and nausea, both of which disappeared in the intervals of pain. There was slight meteorism, and that of the small intestines. During the attacks of pain there was some rigidity of abdominal muscles. No tumor could be felt, though once or twice Dr. Yale thought he could detect some illusive indications of a movable mass. In the intervals of pain the belly was soft, and rubbing gave relief and provoked eructations. No material change occurred in the symptoms during Sunday and Monday. The bowels had been moved by injection, and there had been occasional vomiting and frequent eructations of fluid matter, which was sour, but without any fecal odor. The pain had been controlled by morphia. When I saw the patient, at six o'clock Monday evening, her aspect was not that of serious distress. She had no fever, and her pulse was about 100 and of good quality. She had frequent small eructations of a decidedly fecal odor, and complained of their taste. The belly was soft and not very tumid. The large intestine was not distended, and what meteorism there was was evidently of the small intestines. There was no visible peristalsis. There was no marked tenderness, and the patient allowed free manipulation of the abdomen without complaint. I thought I could feel occasionally the illusive tumor, about the size of a small egg, which Dr. Yale had described, but I could not be sure of it. The urine was scanty, and a specimen which Dr. Yale had procured in the morning contained very numerous plates of cholesterine, and what had the appearance of fragments of undigested muscular fibre. These appearances indicated, what was afterward confirmed by the statement of the patient, the admixture of some fecal matter with the urine. My examination led me to the conviction that the case was one of obstruction of the small intestine, probably high up, and I ventured the opinion—from the history of the two attacks of what corresponded more nearly with those of biliary colic than with anything else, which occurred last autumn; from the presence of so much cholesterine in the fecal matters which were accidentally mixed with the urine; and from the gradual and somewhat subacute evolution of the symptoms of obstruction—that the case was probably one of impacted gall-stone.

I advised surgical counsel without delay, and Dr. Bull saw the patient the same evening at nine o'clock. I will ask Dr. Bull to relate the subsequent history of the case and the details of the laparotomy, which was unavoidably delayed for forty-eight hours.

Dr. Bull continued the case as follows: Monday evening, when I saw the patient with Dr. Yale, the condition was as already described by Dr. Draper; a small stool had been passed voluntarily just before my visit. The fecal matter was formed and of pasty consistence. I also saw about eight ounces of undoubted fluid fecal matter, which had been vomited; wind in small quantity had passed.

Tuesday, February 28th (the following day), was marked by fecal vomiting in the forenoon, and there were two thin movements of material like that vomited, mixed with beef-extract, which had been injected. General condition unchanged. At 3 P.M. Drs. Yale, Draper, and myself agreed that laparotomy was urgently indicated, and so expressed ourselves; but the family desired that so serious a measure should be delayed till further counsel was present. At 10.30 P.M. Dr. Octavius White and Dr. J. Blake White were added to the consultation. There had been no more vomiting, less frequent eructation, and one small liquid evacuation, the character of which was similar to those last passed—a mixture of fecal matter and nourishment. The general condition was unchanged; several nutrient enemata, with whiskey and opium, had been retained. The necessity for operation was still urged, but in deference to the wishes of the family a final decision was postponed till morning.

On the 29th, about 8 A.M., the patient suddenly vomited about half a pint of the same liquid fecal matter, but the nurse did not succeed in catching any in a vessel; no movement had occurred. The failure to demonstrate the character of the last vomiting, since it was not seen by any of the physicians, seemed sufficient reason to the family for further postponement of operative measures. The danger of delay was urged, and it was finally agreed that an operation should be performed in case vomiting occurred again. The pulse at this visit was 100, the temperature 99°, there was little or no pain, and no increase in the tympanites. The indefinite "feel" of a tumor could be appreciated half-way between the navel and the anterior superior spine of the ileum of the left side. The urine in twenty-four hours had increased in quantity. At 4 P.M. the vomiting recurred, and the time for operation was fixed at eight in the evening. The general condition was still good, though during the day the pulse had become more compressible and the patient rather languid, but not decidedly weaker.

It was nine o'clock before the operation was begun, and the general condition had in the five hours' interval changed for the worse. But this change was perceptible only in the appearance of the face. Ether was given at nine o'clock by Dr. Yale. On opening the abdomen by a median incision, four inches in length, the finger was passed through the moderately distended intestines to the cæcal and sigmoid regions. These parts of the colon were empty. I pulled out a loop of distended intestine which occupied the middle line, and at once perceived an empty loop. Traction on this brought to view a part in which a foreign body was firmly arrested. The gut above was fully two and a half inches in diameter, that below about half the size. The presenting intestine was moderately congested, but no fibrinous or fluid exudation was seen. I tried to push the foreign body upward—preferring to make the incision in a part of the gut not so recently subjected to pressure from within—but it was not possible to do so. An incision through the wall of the gut, one and a half inch in length, liberated the body. This incision was made directly opposite the mesenteric border; it was closed at once with fourteen Lembert sutures of carbolized silk. No blood escaped into the cavity. The loop containing the wound, and that first drawn out, were then returned to the abdomen, and the external wound closed. Thirty-two minutes were occupied in finding the body, removing it, and suturing the intestinal wound, and twenty-five in closing the abdominal wound, making the duration of the operation about one hour. Only three ounces of ether were used. There were signs of collapse just after the body was extracted, and these were increased and aggravated by the close of the operation. All possible means were resorted to to bring about reaction, but in vain; death occurred two hours later. The body extracted, which I now show, was a gall-stone, the size of a small horse-chestnut. It measures one and a half inch in its long, and one and three-eighths inch in its short, diameter. One side is flattened, the other rounded, and one extremity presents a circular depression that will accommodate the tip of the little finger.

The following notes were made by Dr. Frank Ferguson, who conducted the autopsy:

Inspection.—Body is fairly nourished. Rigor mortis is well marked. There is no œdema. There is an incised wound in the median line of the abdominal wall, four inches in length, extending from a point one inch above the umbilicus downward, and carefully adjusted by interrupted sutures.

Peritoneum.—The small intestines are distended with gas up to a point six feet from the pylorus, where there is an incised wound in the wall of the jejunum, opposite the mesentery. This wound is one and one-half inch in length, and parallel to the axis of the intestine, and edges carefully adjusted with black silk sutures. The intestine being distended with water, there is no oozing through this wound.

The diaphragm is on a level with the third rib, right side, and with the fourth rib, left side.

Thorax.—There are old adhesions at the apices of the lungs and over upper lobe of right lung in the axillary line.

Heart.—The pericardium is normal. The heart is normal in size. The muscular tissue is flabby and pale-brownish in color. The valves are competent.

Lungs.—The most dependent parts of both lungs, especially the lower lobes, are intensely hyperæmic. The lungs otherwise are normal.

Spleen.—The spleen is normal.

Stomach.—The stomach is normal in location. It is moderately distended with gas, and contains a small amount of fluid blood. Its mucosa is normal. The pylorus is larger than normal, admitting two fingers.

The duodenum and jejunum are very greatly distended with fluid and a small quantity of gas, to the site of incision in the wall of jejunum already alluded to.

The jejunum below the incision, and the ileum. are about the normal size. The cæcum and descending colon are distended with fæces and gas, and the transverse descending colon and rectum are comparatively empty.

As the peritoneal cavity is laid open the coil of small intestine in which the incision was made is free, and not in any way united with neighboring coils; but on either side the serous surfaces of the small intestines are united to each other by recent adhesions. There is no appreciable quantity of lymph, but the peritoneum is hyperæmic, and there is about one-half ounce of purulent fluid in the most dependent portion of the peritoneum on the right side.

The wall of the hepatic flexure of the colon is united firmly to the gall-bladder on the one side, and on the other side of the gall-bladder the duodenum, just below the pylorus, is firmly united.

These adhesions do not readily tear, and in the neighborhood there is no further evidence of inflammation, either old or recent.

On opening the duodenum the common duct is found pervious.

There is an opening in the wall of the duodenum through which a cylinder five-eighths of an inch in diameter passed into the gall-bladder. There is a loss of mucous membrane surrounding this opening in the wall of the duodenum to the extent of one-fourth of an inch in every direction from the edge of the hole, and the edges of this ulcer appear to be healing. The gall-bladder is empty, and its wall, especially the mucosa, is thickened.

Liver.—The liver is rather small, darker in color than normal, and contains a moderate amount of fat. The biliary ducts are not especially distended.

Kidneys.—Normal in size, capsules are adherent, cortices are slightly thinned, markings are normal.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 15, 1888.

Abraham Jacobi, M.D., President, in the Chair.

ON SOME QUESTIONS IN CONNECTION WITH SYPHILIS HEREDITARIA TARDA.

Dr. F. R. Sturgis read a brief paper on this subject, which was of interest, he said, not only to the syphilographer but also to the general practitioner, because it often entered into the question of diagnosis. It was not until within the last twenty-five years that many cases of disease had been assigned to their true place, that is, among those of hereditary syphilis. A most interesting question was whether hereditary syphilis may lie dormant in the system several years before symptoms declare themselves. It was a rule which had been pretty generally accepted among surgeons, that when a patient presented himself with the lesions of the advanced stage, called, erroneously he thought, the tertiary stage of syphilis, he must have had at some time earlier manifestations of syphilis, no matter how much he might deny it. They even went further, and said that the disease began with an initial lesion, although the surgeon had not seen, and perhaps could not find any trace of it. In the earlier days hereditary syphilis was supposed to show itself at birth, either in stillbirth, or in syphilitic manifestations on the skin, etc. It was observed, however, that some infants were apparently in perfect health and well nourished when born, yet in a little while they began to lose appetite, to grow thin, and after a time the eruption broke out which could be assigned to nothing else but syphilis. It was noticed that when the eruptions occurred after birth they took place in a large proportion of cases before the end of the third month. According to tabulated cases, hereditary syphilis gave symptoms of the disease before the third month in as many as three-fourths of all the cases. But it might be objected that some cases did not show any symptoms until later, and the question then arose, how much later?

In replying to this question, Dr. Sturgis turned his attention to cases reported as those of syphilis hereditaria tarda by different European authors, in some of which the first symptoms were said to have manifested themselves at the thirteenth, fifteenth, twenty-first, and twenty-seventh months after birth, and in three cases at the twelfth and fifteenth years. In the three last named the possibility of acquired syphilis had not been excluded. Before considering the other cases, he reviewed the course pursued by hereditary syphilis. The first symptoms might appear shortly after birth as a macular syphilide, the child having before been in good health. Associated with this there might be mucous patches of the mouth and tongue, which after a time disappeared. Then the child assumed the appearance of premature old age peculiar to syphilitic children. There might be a keratitis, and some trouble with sight and hearing. It then went on perhaps to puberty without apparent symptoms of syphilis, when enlargement of the bones, and other symptoms of the disease in the advanced stage developed, and the surgeon, being consulted for the first time, might conclude that this was the first outbreak, whereas the symptoms had existed previously, but had been overlooked. Dr. Sturgis thought that the cases which had been reported as those of late hereditary syphilis were probably either cases of acquired syphilis, those of mistaken diagnosis, or of syphilis in the advanced stage, the earlier symptoms having been overlooked. Often the first symptoms leave some signs of their existence, and often they do not. In the latter event the surgeon has to depend upon the history given by the parents. One of the difficulties in determining whether a case is or is not one of late hereditary syphilis is the possibility of its being the acquired form.

Dr. E. L. Keyes, in reply to the question whether his experience went to show that hereditary syphilis might first manifest itself in adult life, said that he had never seen a case of what could truly be called late hereditary syphilis, although he had seen cases in which it was alleged that the symptoms being treated, the patient being some years of age, were the first which had appeared. But in such cases he had always been able to find cicatrices in mucous membranes, or enlargements or deformities of the bones or joints, or some sign of past syphilitic manifestations. He had kept under observation people who he knew had hereditary syphilis, and had seen symptoms develop after they had reached adolescence and the disease had for a long period remained latent. But he could not recall any case in which a new symptom of hereditary syphilis had made its appearance after the twenty-fifth year of age.

Syphilis, he said, is a disease full of variety and very irregular in its course. To it could be applied only general rules. Syphilis, in his opinion, is largely a matter of soil. He did not believe there is any such thing as bad syphilis and good syphilis. Syphilis sown on varying soil sometimes develops abundant fruit and sometimes very little fruit. This was well illustrated in his early experience at the Hôpital Saint-Louis in two patients, man and woman, one infected by the other; the man had the most frightful syphilis imaginable, while in the woman the disease pursued a mild course. These remarks, he thought, had a general bearing upon the particular question under discussion.

Syphilis is essentially a serious disease in young people; the younger the patient the more serious the disease, for the soil is succulent and the disease develops qualities detrimental to function and destructive of organs. Syphilis of old age, on the contrary, is a very slight and feeble affair. It does not amount to much, as a rule. The later one acquires syphilis, according to his experience, the less serious is the disease. He believed that to be the rule, and consequently it was hard to suppose that a child which came into life with syphilis could escape manifestations of the disease until late in years. Therefore, when in after years congenital syphilis showed symptoms and it was stated they were the first to make their appearance, he believed earlier symptoms had been overlooked.

Dr. Keyes incidentally alluded to treatment of congenital syphilis, and related the case of a child which was born with a pemphigus on the soles and palms; it had the snuffles and most marked effects of the disease, but the general eruption was absent. He gave it a fiftieth of a grain of bichloride of mercury every two hours for two weeks, and afterward every four hours. The child had shown no signs of mercurialization, but had thrived wonderfully. It was then apparently in perfect health.

The statement of the parents could not be relied upon as proof that inherited syphilis had not manifested symptoms in early life.

Dr. P. A. Morrow thought the subject of the paper was a very interesting one, and all the more interesting because it had been comparatively neglected. He thought it was only in the last few years that we had begun to appreciate how far-reaching syphilis might be in its impress upon the organization. He believed, with the author of the paper, that a great many of the morbid conditions which were formerly attributed to scrofula and tuberculosis were undoubtedly the offspring of syphilis. In a great many of these cases, it was impossible to trace the history of the child from its birth up to the time when it was presented to the physician for treatment. He would be much inclined to doubt whether any patient manifesting late evidence of hereditary syphilis had entirely escaped the earlier symptoms.

The ordinary impression was that hereditary syphilis exhausted its force within the first two or three years of life, and that, while occasionally slight symptoms might manifest themselves at second dentition or puberty, yet, practically, the disease was not heard of again. He believed that Bumstead and Taylor, in the last edition of their work, declared that evidence of hereditary syphilis after the twelfth year was so exceedingly rare as to be practically eliminated. Dr. Morrow had examined that day a patient, aged eighteen, who had undoubtedly suffered from hereditary syphilis. The soft palate and palatine arches and portions of the laryngeal structures had been swept away, yet it was impossible to get from this patient a direct history of syphilitic symptoms in early life. The only proof consisted in the lesions left and the fact that the patient had not been exposed to acquired syphilis.

Dr. Morrow was surprised that the author of the paper had not referred to the researches of Fournier, who had been a pioneer in syphilitic pathology. In his recent work he gave the details of two hundred and fifty cases of hereditary syphilis, in a large number of which lesions occurred after the third year, and in some after the twenty-eighth and fiftieth years. Dr. Morrow thought there was nothing improbable in the supposition that hereditary syphilis might endure throughout life. We knew that patients might manifest syphilis five or fifty years after contracting the disease, and, hereditary syphilis being essentially the same disease, there was no reason why it might not also show symptoms late in life.

There were many important phases of this subject, but the author had limited his remarks chiefly to the question whether a child might escape early manifestations of hereditary syphilis and yet suffer later from unmistakable evidences of the disease. So far as his personal experience went, he had treated a great many cases of hereditary syphilis at different ages, and in many of them he had been unable to ascertain any history of early manifestations, but that was only negative evidence. He was inclined to think, from general knowledge of the course of syphilis, that these patients had not escaped early manifestations.

Regarding the administration of mercury to the infant suffering from hereditary syphilis, he had had an extreme case in which the nursing child got no mercury except as it was administered to the mother, yet it regained the appearance of a perfectly healthy child.

Dr. R. W. Taylor said that while he recognized hereditary syphilis as pursuing a more erratic course than the acquired variety, yet he was a firm believer in the view that it always had early manifestations. Such manifestations might be so ephemeral and so little destructive in action as to be overlooked and leave no trace of their existence.

We might expect later lesions of hereditary syphilis up to about the twentieth year. Without desiring to obtrude himself into this discussion, he would venture to say that he was the first in America to call attention to the bone-lesions of syphilis, and bring them out of the great slough of ignorance called scrofula, in the book on bone-syphilis, published in 1876 and based on observations begun about 1870. He had there shown that certain lesions might be looked for in hereditary syphilis up to the age of puberty, among others joint-lesions. In Bumstead and

Taylor's work he had written all of the chapter on hereditary syphilis, and had attempted carefully to bring out all the features of that form of the disease. He thought, however, that when the twenty-first year had been reached it was pretty difficult to show that a lesion was one of hereditary syphilis. He did not doubt that lesions of hereditary syphilis might take place after that date, but he had simply said that it usually occurred so and so, although it might occur thus and thus. He had written the chapter with a precaution in mind against what might have been expected, namely, a tendency afterward to attribute too many conditions to hereditary syphilis, especially should they occur at a late period when no definite history of the disease could be traced, or when the patient should have an object in concealing a history of acquired syphilis.

It was hardly germane to the question raised in the paper, but he would simply say that he had listened with amazement to the experience of Dr. Keyes with syphilis in old people. If ever there was a scourge upon the face of the earth to old people it was syphilis. If they had any lesion or functional disturbance it was apt to complicate and aggravate it.

Dr. L. B. Bangs wished the author had defined more definitely what he meant by syphilis hereditaria tarda, and also by hereditary syphilis. In his own experience with the late lesions of so-called hereditary syphilis, he had almost invariably, after careful inquiry, been able to find a history of some previous lesions. It was his belief that in all the cases there had been earlier symptoms, although the physician might not be able to trace them. He believed with Dr. Keyes that the course of the disease depended upon the soil on which it was sown, but in any case it was syphilis, and might manifest itself in the same way, whether hereditary or acquired.

Dr. H. D. Chapin had recently seen a child, four years of age, with periostitis of each tibia, which, although it looked very grave, responded readily to bichloride of mercury. The child had never had any skin-lesion, nor other symptoms of syphilis, so far as could be learned of its mother and grandmother, with whom it lived.

With regard to the influence of the soil in which the disease was planted, he would say that he had seen many cases of syphilis in children who seemed to thrive on it.

Regarding diathesis, and attributing lesions to syphilis which had formerly been considered scrofulous in origin, he had seen many cases in which to fall back upon syphilis as the cause left one in as great confusion as if the old term scrofula had been used. Anti-syphilitic treatment had had no effect, but the greatest benefit was derived from cod-liver oil and tonics.

Dr. A. S. Hunter cited the case of a lady, aged eighteen, whom he treated about three years ago, for extensive destruction of the nasal bones and soft palate. Her reputation was beyond question, and acquired syphilis could be excluded, yet those who had been with her from infancy denied that she had ever had any treatment pointing to syphilis, until the fifteenth year.

Dr. L. E. Holt had seen many cases of syphilitic lesions in children from five to ten years of age, who had given a history of only very few or no symptoms during infancy, but he had not felt warranted in concluding that there had been no early symptoms, for he believed they were in many cases overlooked. He called attention to one diagnostic mark of syphilis, which he thought was seldom absent, namely, enlargement of the epitrochlear glands.

Dr. D. H. Goodwillie had removed nearly the whole upper jaw in a child, five years of age, for what he took to be syphilitic necrosis, although the history of hereditary syphilis was not clear. The patient recovered so far as this lesion was concerned, but died not long afterward of syphilitic disease of the brain.

The President said he had had this subject brought before the Academy, because of its great interest to the general profession. If there was any disease which threw its shadow over the whole future life of the patient, it was syphilis.

Regarding the difficulty of diagnosis in the class of cases under discussion, he thought it was not always possible, even when syphilis showed itself at birth, to make the diagnosis. He alluded particularly to bone-lesions and lesions of the cartilages. It was often difficult to distinguish between syphilitic and rachitic lesions of the bones and cartilages, and it was because of their value as bearing on these questions in particular that Taylor's writings were frequently quoted in Europe and Fournier's in America. It was well to remember the offspring of syphilitic parents usually showed less and less marked symptoms of the affection as they receded from the time at which the parents had become infected, but it might break out later in such patients as rachitis, and it would be difficult to define the condition in these instances as hereditary syphilis. It was a peculiar fact that the cases in which hereditary syphilis was reported to have first manifested itself at an advanced age had been reported only by the older writers. In reading over the writings of recent observers, as Burke, Diday, and others, he had found none of them willing to commit themselves to the view that hereditary syphilis might first appear at a late age.

Another difficulty which he had found in investigating this subject was the fact that some years ago, thirty or fifty, it was extremely common to administer mercury whatever might be the occasion for it, and this, as was now known, would have been likely to obscure any history of early hereditary syphilis.

The President had seen one case in which known hereditary syphilis had caused caries of the hard palate and bones of the nose and destruction of soft parts after the fifteenth year.

Dr. Sturgis, in closing the discussion, said he had not given his own experience in the paper, preferring to wait and hear that of others, but he would now say that he did not believe cases of hereditary syphilis remained latent, to produce symptoms at puberty or a later period. In answer to Dr. Bangs' question, he said he understood hereditary syphilis to mean that which the child derived from its parents before birth. As to late lesions, if they occurred not until after the fifth year they would be regarded as cases of syphilis hereditaria tarda. His attention had been more especially called to the subject from the fact that he had recently seen a young man, seventeen years of age, with cold inflammation of the knee, which resisted all treatment until the anti-syphilitic was adopted. No history of syphilis could be obtained, until he found the remains of an old keratitis. He thought mild lesions of syphilis often occurred in children, which were overlooked and not treated, and it was in the untreated cases that late lesions were very apt to develop. The child might go along until about the fifth year, and then have some trouble with the joints, ears, or eyes. The longer the time after the tenth year at which symptoms of syphilis made their appearance, the more suspicious he became that the disease was acquired. With regard to the diagnosis between scrofula and syphilis, in syphilis the child was often apparently well nourished. In this disease cod-liver oil and tonics were useless beyond a certain point, whereas iodide of potassium would cause the lesions to heal after other measures had failed.

Dr. Sturgis said that in hereditary syphilis there were likely to be renewed manifestations of the disease about the fifth year, and again at the period of puberty. But if lesions occurred not until after that period it was very probable they were the result of acquired syphilis.

The Treatment of Furuncles.—Dr. F. W. Carmon, of this city, writes: "I notice in your last issue an article on the abortive treatment of furuncles, which leads me to say that I have many times used the extract of belladonna with sufficient glycerine to form a paste, for the same purpose, and have never known it to fail even if applied for eight or ten hours only."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 26, 1888.

LAURENCE JOHNSON, M.D., PRESIDENT, IN THE CHAIR.

DR. L. E. HOLT read a paper (see p. 385) on

CEREBRAL SYMPTOMS OF PNEUMONIA IN CHILDREN.

DR. A. H. SMITH thought the cases of pneumonia with cerebral symptoms might be divided into three classes; namely, those in which the cerebral symptoms were brought about by the direct influence of the pneumonic poison, those which were the result of high temperature, and those which were the result of exhaustion.

He regarded lobular pneumonia as essentially an infectious disease, due to a specific poison, as truly as were the exanthemata. In young subjects initial cerebral symptoms, especially convulsions, took the place of the chill in older people. He thought it probable many cases of broncho-pneumonia were of a mixed type, and therefore possessed infectious characters. While he regarded early convulsions as being produced by the poison of the disease, those occurring late in the progress of the case were probably caused by exhaustion. Nearly all cases in which convulsions took place late in the disease proved fatal, for the reason that the convulsions were due to a degree of exhaustion which was of itself incompatible, as a rule, with prolongation of life.

He was inclined to ascribe most cases of delirium to high temperature. Usually the delirium ceased or diminished in proportion to the moderation of the temperature. Later in the case the delirium might result from exhaustion. At this period there might be cerebral symptoms of a typhoid type. There was one other factor whose exact influence in the production of cerebral symptoms it was difficult to determine, viz., kidney disturbance. In a large number of cases of pneumonia, no less in children than in adults, there was albuminuria and deranged renal function. It was quite possible this might contribute somewhat to the cerebral symptoms.

Gastro-intestinal disturbances also exerted an influence in the causation of cerebral symptoms. He would include vomiting among the cerebral symptoms, for the same reason that he so regarded it in the exanthemata.

Regarding treatment, he bore testimony to the value of antipyrine employed, not for the purpose of reducing the temperature, but to allay restlessness and induce sleep.

DR. JOSEPH E. WINTERS had expected less from the title of the paper than he had heard. For several years he had been unable to understand why it was stated in the text-books that there was special liability to cerebral symptoms in pneumonia of the apex in children. He agreed with Dr. Holt that cerebral symptoms were more common in extensive pneumonia.

Dr. Winters doubted whether a convulsion would be found to occur at the commencement of pneumonia in children without one of the following predisposing causes: (1) The occurrence of convulsions previously, establishing, as it were, the convulsive habit; (2) inherited neurotic habit; (3) some auditory trouble induced or aggravated by the cause of the pneumonia. He had yet to see a case which he could not trace to one of these three causes. He agreed with the author, that the occurrence of a convulsion at the onset of a pneumonia had no influence on the prognosis. As far as it concerned the convulsion, his treatment was directed to the predisposing cause.

He further coincided in the view that in central pneumonia an earlier diagnosis would more commonly be made if physicians were in the habit of carefully examining the chest in all doubtful cases. By raising the child's arms and listening to the sounds in the axillar spaces, central pneumonia could be detected early.

DR. AUGUST SEIBERT thought the paper of Dr. Holt was a very neat contribution to our definite knowledge of pneumonia in children. Dr. A. H. Smith had anticipated some of the remarks which he had intended to make. The statistics given went to prove, he thought, that convulsions due to fibrinous pneumonia occurred early in the disease, and were the result of the poison and of the high temperature. As to the influence of the high temperature, however, he believed it had little to do with causing the convulsion. The convulsions which had occurred in broncho-pneumonia had come on late in the disease, and were the result, he thought, of exhaustion, paralysis, or watery exudation in the brain. As to high temperature being the cause of the delirium or convulsions, this would seem not to be true, for in many other conditions the temperature rose higher, and continued high for a longer period, without causing either delirium or convulsions. This was true of a series of cases of gastritis in children which he published about two years ago.

DR. H. D. CHAPIN said that, in the cases of pneumonia accompanied by convulsions which had come under his observation, there had been high temperature. When the temperature fell the convulsions ceased. He believed with a previous speaker that the early convulsion in children corresponded to the chill in the adult. Whether it was due to a germ he could not say. As to the frequent occurrence of cerebral symptoms in pneumonia of the apex in children, he was not yet ready to discredit the statement of the text-books on that point. In all the cases of pneumonia of the apex which had come under his observation there had been cerebral symptoms, usually, however, of stupor rather than of convulsions.

As to treatment, he could fully indorse what Dr. Holt had said regarding the use of cold applications. After the temperature had fallen several degrees from applications of cold cloths to the chest (warmth being applied to the extremities), the child breathed slower, was made more comfortable, and was enabled to sleep. That being true, he thought antipyrine was not required for the purpose for which Dr. Holt administered it. It tended to weaken the heart, and in pneumonia in children heart failure was much to be feared. He had employed antipyrine in only two cases, and he had the impression it had hastened death.

DR. A. CAILLÉ remarked that many diseases, especially the acute infectious diseases, were ushered in occasionally by cerebral symptoms, and to this rule pneumonia in children was not an exception. From twenty-four to forty-eight hours were usually required to locate an inflammatory trouble in the lungs, and it was not rare before that time to have cerebral symptoms. It was interesting to learn why they should occur in some cases and not in others. He thought it probable that the intensity of the disease was a cause of the cerebral symptoms. The cerebral symptoms which occurred at the beginning, and those which occurred toward the close of a pneumonia, were due to entirely different causes; the former probably to hyperæmia, and the latter to inanition of the brain. In three or four cases of pneumonia, ushered in with cerebral symptoms, he had observed that both pupils were unusually large, but reacted to light. In other cases, not ushered in by cerebral symptoms, the pupils were not so large. He could not say whether this observation was at all significant. He believed in the cold pack.

DR. SARAH J. MCNUTT's experience had been like that of Dr. Holt, that cerebral symptoms had not been specially limited to cases of pneumonia in the apex. Her observations corresponded with those stated in Dr. Smith's book, that cerebral symptoms were just as apt to occur in well-developed children as in those who had inherited a nervous temperament. She had noticed that, in a number of cases attended by cerebral symptoms, there was constipation, catarrhal jaundice, or some gastric disturbance. She had seen an epidemic of lobar pneumonia break out in an institution after the introduction of a case from without.

Regarding treatment, she had used the cold pack very frequently, and had found it quite valuable, particularly in broncho-pneumonia. In the later stage, with tendency to heart failure, musk had been of great service.

Dr. J. A. Irwin said that in his experience the localization of the pneumonia had little to do with the cerebral symptoms, which were, as far as he knew, almost entirely reflex. In the obscure cases of central pneumonia reflex nervous symptoms were most marked, and in many of those cases the cerebral symptoms threatened life before the diagnosis could possibly be made from the physical signs. The diagnosis, he thought, was usually made in those cases from symptoms. He expressed disagreement with those physicians who attached extreme importance to exact diagnosis. Having determined the existence of pneumonia, that physician, he thought, would be most successful with his cases who based his treatment on symptoms, and avoided the dangers incurrred by frequent physical examinations of the chest and disturbances incident to conflicting opinions of consultants. Having made the diagnosis of pneumonia, and localized it more or less definitely, he gave his patient rest and treated symptoms as they arose.

He had observed that those children whose nervous systems were most sensitive to eccentric diseases often had the greatest reactionary power. Regarding cerebral symptoms in the pneumonia of children, he had observed them most frequently in obscure central pneumonia. In the catarrhal type, usually bronchitic in the beginning, late cerebral symptoms were the precursors of death.

Dr. David P. Austin had found in treatment much benefit from the oil of theobroma used as an inunction. It acted as a nutrient, and several hours after its use the temperature often fell two or three degrees, and the child was enabled to sleep.

The President could not harmonize the theory of the infectious nature of pneumonia with the prevalence of the disease almost as an epidemic in certain weather, as in January of this year; in other kinds of weather, such as that in February, when it was clear and cold, its prevalence was greatly diminished.

He had heard Dr. Seibert's paper on this subject some months ago, but while it had greatly interested him, he had not been convinced on all the points made.

Dr. Holt, in closing the discussion, said it was not his intention to speak of the pathology, but he would say that, while some cases of pneumonia in children had resembled very closely in their clinical aspect those of lobular pneumonia, yet, microscopically, they differed very little from disseminated pneumonia. Vomiting was associated in nearly all cases with cerebral symptoms, but it also occurred in a large number of cases in which there were no cerebral symptoms. He often found convulsions not associated with high temperature. He thought it was a pretty well established fact that, whatever might be the cause of a convulsion, the temperature was likely to rise; but might not the convulsion be the cause of the rise in temperature rather than the result? It was not at all uncommon to have a temperature in children of 105° F., long continued, without convulsions, or even much discomfort. Regarding the dangers of antipyrine, he had used it a great deal, and had never had any ill result. Regarding Dr. Caillé's remarks as to dilatation of the pupils in some cases of pneumonia ushered in with cerebral symptoms, he had in a few instances observed the same fact. When he spoke of repeated examinations of the chest, he meant only for diagnostic purposes. Cacao-butter was of great value in prolonged cases of pneumonia, in rendering the patient comfortable. As to its being the cause of a fall in temperature, that might result in the time given by Dr. Austin without any medication.

OUR LONDON LETTER.

(From our Special Correspondent.)

ARMY MEDICAL OFFICERS AND THEIR GRIEVANCES—THE OPERATIVE TREATMENT OF UNREDUCED DISLOCATIONS—THE MILROY LECTURES—YELLOW FEVER NOT CONTAGIOUS—THE PRESIDENCY OF THE COLLEGE OF PHYSICIANS.

London, March 17, 1888.

One of the most important questions of the day is that of the efficiency of our naval and military establishments, as to which important debates have lately taken place in the House of Commons. The army medical department has received its fair meed of criticism, and the interests of army medical officers are somewhat at stake. The question of "rank" has not yet been settled in a manner satisfactory to those concerned. That of "pay" has been indirectly raised by the attack which has been made upon the expenses of the army medical department. A new step has just been taken which may affect army surgeons to no inconsiderable extent, viz., the issue of a royal warrant establishing a "reserve" of army medical officers. Enrolment in this corps is, it appears, to be voluntary, those joining it being drawn from the medical officers of the militia, yeomanry cavalry, and volunteers. Those joining will be liable to be called out for service at home in times of great national emergency, and may also have to undertake medical charge of troops quartered in their district in ordinary times of peace. It is feared that this may prove to be the prelude to a considerable diminution in numbers of the army medical officers on home service, which means, of course, that the proportion of their term of service which is spent abroad will be increased. Altogether, it looks as if harder times were in store for army doctors, and, taken in conjunction with the unsettled "rank" question and rumors of worse pay, this cannot but render the service less popular.

At the last meeting of the Clinical Society several cases were brought forward in which operative measures for the relief of unreduced dislocations had been successfully undertaken. Among these was one brought forward by Mr. Croft, of St. Thomas' Hospital. It was that of a workingman, aged thirty-nine, who was admitted into the hospital for symptoms of dislocation of the internal semilunar cartilage of the right knee-joint. The joint had been attacked by rheumatic inflammation eight years previously, but its movements had not thereby been permanently impaired. It had been rendered completely useless by the accident, which had occurred three weeks previous to the patient's admission. It was decided to perform Annandale's operation with antiseptic precautions. The cartilage was found attached at its anterior and posterior extremities, but to have been torn from its intermediate connections. Its remaining attachments were divided and the cartilage removed from the joint, which was then closed and drainage provided for. The man was discharged cured on the fortieth day after the operation, and when seen four months later was in full work. Mr. Annandale, who was present, said he had operated in five cases, and the result had been perfect in all. He used no drainage-tube, finding it unnecessary. He did not venture to move the joint till six weeks after the operation, and at first used passive movement only.

At the Medical and Chirurgical Society, Mr. Sheild, of Charing Cross Hospital, narrated the case of a man, aged forty-five, who was admitted into the hospital suffering from an unreduced subcoracoid dislocation of the left humerus of twelve weeks' standing. There were symptoms of pressure on the median and ulnar nerves, the hand being almost useless. The radial pulse was also lessened in force. It was found impossible to effect reduction under ether, so the head of the humerus was excised at the level of the anatomical neck. The use of the limb was rapidly regained, and twelve weeks after the operation the patient was able to follow his employment as a waiter. Remarking on the disastrous results of forcible manipulations of old dislocations of the shoulder, Mr. Sheild suggested that excision of the head of the bone was preferable in cases such as the one he had narrated, when pain was severe, the displaced bone fixed, and symptoms of nerve-pressure marked. Mr. Hulke congratulated Mr. Sheild on his case, but observed that the procedure was not novel, it having been advocated long ago by Von Langenbeck, and laid down as the standard practice by Hüter and others in German text-books. Mr. William Adams referred to some cases of his own, in which he had successfully operated. Mr. Howard Marsh related a case which ended less favorably. It was that of a similar unreduced dislocation, in which there was much wasting of the muscles and excruciating pain for a long time. The patient was admitted into St. Bartholomew's Hospital, and Mr. Morrant Baker broke down many close adhesions; but without relief. The case then came under his own care, and he endeavored to stretch the brachial plexus. This proved a very difficult operation, and also gave no relief. After that Mr. Savory removed the head of the humerus, but the pain remained about as bad as ever. Mr. Timothy Holmes said he had always maintained that in certain cases of unreduced dislocation excision was the best method of treatment. Subcutaneous section of the bone was, he thought, more dangerous than open excision, considering the number of important vessels and nerves in the axilla. Dislocation might cause much injury to vessels, as in a case which he had brought before the Clinical Society in which the artery was bruised and leaked. The patient would not submit to excision of the head of the bone, and death ultimately resulted.

In the Milroy Lectures, lately delivered at the College of Physicians, Inspector-General Lawson devoted most of his time to the consideration of yellow fever. After describing the course of different epidemics, the symptoms of the disease were detailed. The question of the contagiousness of the disease was then considered. In order to establish the fact of contagion in any given cases it was clearly necessary, said the lecturer, to exclude the possibility of the outbreak having arisen from local causes. In the great majority of cases said to have arisen from contagion, no such attempt to exclude local causes had been made, and, when legitimately interpreted, the evidence was quite insufficient to establish the conclusion based on it. As Inspector-General Lawson has had fifty-four years' professional experience, including many years' service as an army surgeon in all parts of the globe, some weight may justly be attached to the opinion thus expressed by him.

In spite of his recent illness I understand that Sir William Gull is by no means an impossible candidate for the presidency of the College of Physicians. I do not mean by this that he will announce himself as a candidate, for avowed candidature and open canvassing are alike not permissible. It is, however, by no means improbable that the majority of the Fellows may determine to elect him. At any rate, the choice seems now to lie between him and Sir Andrew Clark, for Sir Henry Pitman announces that he will decline the presidency even if elected to it.

DR. THOMAS' CASE OF "TUBAL PREGNANCY ADVANCING TO FULL TERM WITHOUT RUPTURE."

To the Editor of The Medical Record.

Sir: Will you allow me to suggest that the above case was one of the well-known variety where the primary rupture took place at the lower part of the tube and into the cavity of the broad ligament. Dezenneris named it the "sousperitoneo-pelvicum variety" and Berry Hart has completely elucidated its anatomy.

I deeply regret the fatal case of Lawson Tait's operation for ruptured perineum, related by Dr. Paul Mundé, and I agree with him; the result was probably aided by the very deep wound. He recommends that the septum be split not more than half an inch. I never make the split so deep as that, rarely more than a quarter of an inch.

I am, etc.,

Lawson Tait.

Birmingham, March 16.

SHALL A SURGICAL INSTRUMENT BE PATENTED?

To the Editor of The Medical Record.

Sir: In The Record of March 17th there is quoted the oath of Hippocrates, according to which it is dishonorable to cut for stone.

The clause in the Code of Ethics in relation to the patenting of instruments has the same relation to current civilization as the Hippocratic oath.

Patent-right and copy-right stand on the same basis, and one should be considered as honorable as the other.

It is often the case that the medical profession needs to be protected against the imposition of instruments made in a different manner from the original invention, but sold as true copies.

Nothing but a patent will protect the profession from this kind of imposition.

Very few instruments will pay the cost of patenting; but an inventor does not like to see the reputation of his instrument destroyed by imperfect copies which will disappoint those who buy them.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 31, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	17	6
Scarlet fever	168	25
Cerebro-spinal meningitis	2	1
Measles	47	2
Diphtheria	129	46
Small-pox	23	4
Yellow fever	0	0
Cholera	0	0

Skin Eruptions Following the Administration of Drugs.—Dr. Oscar A. Fliesburg, of Hudson, Wis., writes: "In your issue of March 3d you have an article with the caption 'Unusual Effects from Salol.' On several occasions I have found salol produce an herpetic eruption, but I have not been obliged to stop the administration on that account, as the eruption has proved itself to be of a very ephemeral character. But I am not sure that in this particular instance the salol was the cause, as I have, during the fall and winter, seen no less than five distinct cases of typhoid fever with the identical herpetic eruption, extending over the whole chest, and reaching sometimes as far back as the spine, and downward in two cases over the whole abdomen, into the 'fossæ iliacæ.' The eruption resembled a diffused miliaria, herpes iris, or, in one case, hydroa. It has appeared during the administration of quinine, acetanilide, and of salicylate of ammonium, together with hydrochloric acid and strychnia, alternately given. It was of a very transient duration, seldom lasting more than twenty-four to forty-eight hours. Considering that it has appeared under the administration of so many different drugs, I hardly believe that it has been caused by any of them, but that, instead, it is a symptom, under certain conditions, of the fever; and I believe that it was so in Dr. Church's case."

THE CARTWRIGHT LECTURES ON THE GENERAL PATHOLOGY OF FEVER.[1]

By WILLIAM H. WELCH, M.D.,

PROFESSOR OF PATHOLOGY IN JOHNS HOPKINS UNIVERSITY, BALTIMORE.

Lecture II.

The Effects of Increased Temperature of the Body.

In the last lecture I endeavored to bring before you the main facts which we possess bearing upon the explanation of febrile rise of temperature. After a review of our knowledge concerning heat production, heat dissipation, and heat regulation in fever, we were led to the conclusion that neither the changes hitherto observed in the production of heat, nor those in the loss of heat, suffice to explain febrile temperatures. Such an explanation seemed possible only upon the assumption that the fever-producing agents act either directly or indirectly upon the nervous mechanism, controlling the relations to each other of the production and the discharge of heat. We then turned our attention to the relations of the nervous system to these processes, and found that the investigations of recent years have enabled us to obtain a much clearer conception than was formerly possible of the manner in which the complicated heat relations in fever may be brought about by an action upon the nervous system. We found even substantial experimental basis in support of clinical facts which show that circumscribed lesions of certain parts of the central nervous system may induce directly febrile disturbances of animal heat.

To carry the subject further, to consider whether pyrogenic agents act primarily or only secondarily upon the processes concerned in heat production, or upon those concerned in heat dissipation, or upon the apparatus regulating the relations to each other of these two sets of processes; to discuss whether these agents act directly upon the central nervous system, and if so, upon what part, or upon the peripheral nerves or their terminations, or upon the tissues; to follow out more fully than we have done hitherto the themes here suggested, would lead us, with our present knowledge, into a sea of speculation. We should find only here and there a faint light of fact to guide us. Even upon foundations as insecure as this, speculations have their legitimate uses. A good hypothesis is a most valuable incentive to scientific work. It is not my purpose, however, to carry you with me further in this direction, although I realize that a single lecture has been far from sufficient for a satisfactory exposition of the subject.

After dismissing the considerations bearing upon the so-called theory of fever, there still remain a host of questions properly belonging to our subject. It is evidently impossible, even if it were desirable, that these lectures should include a discussion of all of these questions. I have, therefore, selected certain ones, partly because they seem to me of immediate interest, and partly because I have given some attention to their study.

In the present lecture I wish to present to you some observations concerning the relation of elevation of temperature to other disorders of fever, and as to the question how far increased temperature is a source of danger in fevers.

Here I may repeat that the word fever is used as a convenient name for a group of symptoms commonly associated together in febrile diseases. The association of these symptoms, however, is so loose that we regard only the dominant one, the increased temperature, as the essential criterion of the existence of fever. It saves circumlocution to adopt this somewhat vague and common signification of the term fever, although I think it would be an improvement to confine the term to abnormal elevation of temperature. The literature of fever is full of misapprehensions resulting from the various meanings attached to the word by different authors.

All of the bodily functions may be disordered in fevers. The various symptoms, or classes of symptoms, which are so commonly associated as to be regarded by many as belonging to the febrile process are, in addition to heightened temperature, increased frequency of the pulse and other circulatory disturbances, increased rapidity of respiration, muscular weakness, lessened secretions, disordered nutrition and digestion, and nervous symptoms.

What is the connection, if any, between these symptoms and the elevation of temperature? What degrees of elevated temperature are dangerous to life, and in what does the danger consist? This subject can at least claim the interest that attaches to the questions of the day. The various opinions which have been held by clinicians on these points are too well known to you to require an historical review. I need only remind you that until within a few years the views advocated with especial force for nearly thirty years by Liebermeister have prevailed, although not without considerable opposition. According to these views the chief source of danger in uncomplicated essential fevers is the elevation of temperature, and the main indication for treatment is the reduction of temperature. Above all it was urged, with apparently convincing arguments, that the weakness of the heart, which is undoubtedly one of the gravest dangers of fevers, is the direct effect of prolonged high temperature, and is manifested anatomically by parenchymatous or fatty degeneration of the cardiac muscle. Liebermeister sharply defined his position when he said, "A man whose temperature measures continuously 104° F. (40° C.), or more, surely dies in consequence of the elevation of temperature, one in a few days, another after a somewhat longer time, according to the resistance of the individual." "If his temperature reaches 108.5° F. (42.5° C.), or more, then he is irrecoverably lost."[1]

At the present moment there is a decided reaction against these views, a reaction which in some quarters goes to the extent, not only of denying that there is danger in febrile temperatures which do not exceed a very high point, but of asserting that the elevation of temperature is a beneficent provision, a most important *vis medicatrix naturæ*, which should not be checked by the interference of the physician. This reaction of opinion is plainly due in great part to the disappointment which has followed the high hopes raised by the discovery of a number of drugs which are admirable antithermic agents, and nevertheless do not exert over febrile diseases that controlling influence which had been anticipated.

These questions, you may say, are clinical ones and not much edification is to be expected from their discussion by a pathologist. So far as the propriety of the use of antipyretic agents, or of any other mode of treatment in fever is concerned, it is true that the decision must be reached at the bedside, and cannot and never should be controlled by the results of experimental pathology. But an appeal has properly been made to experimental pathology to shed light upon such questions as the effects of heat upon the functions of the whole body and of its various organs, and upon the causes of parenchymatous and fatty degenerations. The arguments advanced in support of the view that all of the characteristic symptoms of fever are directly dependent upon the increase of temperature, and that high temperature is the chief source of danger, are derived no less from experimental pathology than from clinical observations.

---

[1] Delivered at the College of Physicians and Surgeons, New York, April 5, 1888.

[1] Liebermeister: Volkmann's Sammlung, No. 31, p. 240.

Three methods have been employed to determine the effects of increased temperature in fever: one is to study the effects of heat upon animals; the second is to examine in different fevers and in different cases of the same fever the relation of the temperature to the other symptoms and to the general condition of the patient; and the third is to note the influence of reduction of temperature upon these symptoms.

Each method has its limitations. The condition produced by exposure to external heat, even if it be called thermic fever, is something quite different from ordinary fevers, and we cannot transfer the results obtained by this method directly to the explanation of febrile phenomena. On the other hand, in the clinical study of fevers it is very difficult, and often an arbitrary matter, to separate the effects of increased temperature from those of other factors nearly always present. Hence we find no agreement of opinion among physicians as to what symptoms or lesions in fever are referable to the heightened temperature, and what are due to infectious or other conditions often present. Even the frequent or constant association of certain symptoms with elevated temperatures, and their subsidence or disappearance by reduction of temperature, do not justify us in inferring that the high temperature is the cause of the symptoms, for both may be co-ordinate effects of the same cause, and the so-called antipyretic treatment may influence other conditions as well as the temperature. As has been frequently said of late, the high temperature may be rather an index of the severity of the disease than a source of danger in itself.[1]

The most direct way of determining the influence of heat upon the body is to raise the internal temperature by external application of heat. Here we are not disturbed by the presence of other factors, such as infection, which render doubtful so many of the conclusions derived from clinical observations as to the effects of high temperatures For the solution of many problems it is evidently irrelevant whether the source of heat be within or without the body. These experiments, if properly conducted, are calculated to shed much light upon many questions relating to the effects of febrile temperatures.

According to the testimony of all experimenters, a mammalian animal artificially heated dies when its internal temperature reaches 111.2°–113° F. (44°–45° C.). Death is preceded by convulsions, and immediately or soon after death rigor mortis appears. At the moment of death the irritability of the heart and muscles ceases. Death seems to be due to heart paralysis, and the cause of this is usually set down as heat rigor; but this is not probable, as death generally occurs at a temperature several degrees below that at which rigor of the heart-muscle appears.

It is generally argued that temperatures several degrees below those which are fatal must exert toxic effects, and this conclusion seemed to be substantiated by the majority of experimenters who found that animals whose temperatures were artificially raised to 105°–107° F. (40.6°–41.7° C.), or even to a lower point, manifested signs of illness. These latter results, however, are opposed by those obtained by Rosenthal and especially by Naunyn,[1] who points out that the conditions in most previous experiments were not favorable, as the animals were generally placed in small, dark, poorly ventilated metallic boxes. Naunyn succeeded in keeping a rabbit alive for thirteen days with an average temperature of 106.7° F. (41.5°C.).

Following Naunyn's example, I have had constructed a wooden box three feet long, two feet high, and two feet broad, which fits closely within a double-walled galvanized iron box. The wooden box is provided with a perforated movable bottom, which allows the urine to escape. The space between the two walls of the iron box measures three inches across, and is filled with water, which, therefore, surrounds the inner box on all sides, except at the top, which is left open. The dimensions of this apparatus are somewhat larger than those of Naunyn's heating-box. A folded woollen blanket was drawn over each end of the box, so as to leave uncovered at least one-third, and generally more, of the top. A rose-burner placed underneath served to heat the box. At first a thermo-regulator was employed, but this was found unnecessary as the temperature of the room varied but little, and there was no difficulty in keeping a sufficiently constant temperature in the box. The experiments were made upon rabbits, and only a single one was placed in the box at a time. Corrected thermometers were used. The temperature of the box was taken a short distance above the bottom, and that of the rabbit at a depth of three to four inches in the rectum. This occasion does not seem an appropriate one to describe these experiments in detail with their protocols. I shall take another opportunity for that, and at present give only a general account of those results which relate to the subject before us.

In the box described, I have succeeded in keeping, for three weeks, two large black rabbits, the one with an average rectal temperature of 107.3° F. (41.8° C.), the other with an average temperature of 106.6° F. (41.4° C.). The rectal temperature fluctuated usually between 105.5° and 108° F. (40.8° and 42.2° C.), scarcely ever sinking below 105° F. (40.5° C.), but occasionally rising as high as 109.5° F. (43.1° C.). The temperature of the box varied between 96 and 106° F. (35.5° and 41.1° C.). The rabbits lay most of the time stretched out, breathing very rapidly. They took their food greedily and did not appear ill. At the end of the experiment the first animal was removed from the box, and appearing perfectly well for ten days afterward, it was used for another experiment; the second animal was killed at the end of the experiment and presented marked fatty degeneration of the heart, liver, and kidneys. Both animals lost weight while in the box.

In these and similar experiments the rabbits were given only moist, green fodder, and were allowed to drink plenty of water, which they took eagerly. It is important, for the success of the experiment, that the temperature should be gradually and not suddenly raised.

Different animals offer varying degrees of resistance to the effects of high external temperatures. It has seemed to me that black and gray rabbits surpass in this respect white rabbits. The same temperature of the box does not produce in all cases the same rectal temperature in different animals, or in the same animal at different times. No factor is of more importance in determining the effects of external heat than the animal's power of temperature regulation. Failure of this power is manifested by a sudden rise of internal temperature, which may quickly attain a point incompatible with life. This event may take place without any alteration in the box temperature. The degree of internal temperature at which this paralysis of heat regulation occurs varies in different animals. One may be able to hold his temperature from further rise at as high a point as 109.5° F. (43.1° C.); in another, after the temperature has reached 107.6° F. (41.5° C.) there may occur, without any change in the box temperature, a sudden and often fatal elevation of temperature. In general, temperatures between 108° and 109° F. (42.2° and 42.8° C.) may be regarded as critical temperatures for these animals. One is forcibly reminded by these sudden and dangerous elevations of temperature, of the occurrence of hyperpyrexia in certain fevers of human beings, and there is reason to believe that this, too, is caused by paralysis of heat regulation.

---

[1] In hyperpyrexia and in many cases of insolation there can be no doubt that the high temperatures, as such, are the main elements of danger. But both of these conditions have important points of distinction from ordinary febrile processes. In hyperpyrexia there is probably almost complete paralysis of heat regulation, and we shall find that an analogous condition, with similar dangers, sometimes develops in animals artificially heated. The cases of insolation in which the high temperature is so dangerous are analogous to the condition which may be produced in animals by brusque elevation of the bodily temperature through exposure to heat, and which differs from that resulting from more gradual increase of temperature.

[1] Rosenthal: Zur Kenntniss d. Wärmeregulirung, u.s.w. Erlangen, 1872. Naunyn: Archiv f. exp. Path. u. Pharm., Bd. xviii.

It seemed to me of some practical interest to determine what effect upon the rabbit's power of resisting high temperatures is exerted by exhausting influences, particularly by anæmia. For this purpose rabbits which had been moderately bled, and others which had been used for some other experiments, were placed in the hot box. It was found that these animals are, although not without occasional exceptions, unmistakably less resistant to the effects of high temperatures than are robust animals. They succumb sooner and at lower box temperatures.

We may now consider what inferences may be drawn from these and similar experiments as to the effects of high temperatures. It seems clear that a considerable part of the current arguments based upon experiments concerning the injurious effects of high temperatures must be revised, in the light of Naunyn's experiments, and of those which I have briefly related. Because an animal may be killed by raising its temperature to 111°–113° F. (43.9°–45° C.), it does not follow that an increase of temperature of four or five degrees above the normal involves danger to life or even any serious disturbance of the functions of the body. Although experiments in hot-air chambers show that in man brusque elevations of the temperature by only a few degrees give rise to serious symptoms, Krishaber[1] found that by habituation his temperature could be raised to 106.5°–107.2° F. (41.4°–41.8° C.) without much discomfort. As small animals generally succumb more readily than large ones to artificial heating, it is not likely that the power of resistance in human beings is less than that found to exist in rabbits, and there is reason to believe that it is greater.

We cannot transfer directly to human beings the highest temperatures at which we found rabbits can exist without serious discomfort, save increased respiration. A rabbit's temperature is normally considerably higher than that of man, and apparently slight causes suffice to produce marked fluctuations. The normal rectal temperature of the rabbits used in my experiments was generally between 102° and 103° F. (38.9° and 39.4° C.). The highest average temperature at which a rabbit was kept for three weeks in the hot box exceeded, therefore, by four to five degrees F. the average normal temperature. Such an increase would not correspond to a high febrile temperature in man. We can, however, with equal, and probably greater propriety, compare this temperature with that at which death surely occurs in a condition bordering on heat rigor. This temperature (111°–113° F.) is probably about the same for man as for rabbits and other mammalians. From this point of view the inference may be drawn, although, of course, with much reserve, that human beings may tolerate temperatures of 107° F. (41.7° C.) or even higher, for a considerable time. This inference is supported by clinical observations, especially in cases of relapsing fever.

As already pointed out, the condition produced by artificial heating is not directly comparable with that in fever. In the former the loss of heat from the body is reduced to a minimum; the superficial temperature is three or more degrees higher than the internal, so that the average temperature of the whole body is higher than in fever with the same internal temperature. We cannot say, therefore, but that man may tolerate considerably higher internal temperatures when the elevation is brought about under conditions in which the discharge of heat is not checked than when the temperature is forced up by stopping heat dissipation. This would be proven if confidence could be placed in the enormous elevation of temperature reported by Teale and others. In these cases, however, even if authenticated, it is probable that heat is abnormally distributed in the body, and we cannot infer that the internal temperature is uniformly raised to such paradoxical heights.

It is of the utmost importance to bear in mind that, as my experiments have shown, not only do animals differ in their power of tolerating high temperatures of the body, but this resistance may be weakened by various depressing causes. Nothing would be more irrational than to conclude because one individual in a certain condition can tolerate very high temperature, another in a different condition possesses the same power. In fevers we have various factors, particularly infection, which we may well believe can lower the tolerance of high temperatures. That in some fevers, particularly relapsing fever, this does not appear, or only partially, does not disprove that in another fever, such as typhoid or pneumonia, the system may be placed by other factors of the disease in such a condition that even moderately high temperatures are injurious. It does not seem to me proper in these cases to lay, as some seem inclined to do, the sole stress upon the element of infection. This is, in all likelihood, the determining factor, but the practitioner cannot shut his eyes to the possibility that under its influence the high temperature, as such, is a source of danger to his patient.

With these restrictions I shall surely not be misunderstood when I assert that temperatures which are ranked as high febrile temperatures do not in themselves, independently of other factors, exert any such injurious influence as has been usually attributed to them.

Our attention up to this point has been directed to the effects of high temperatures upon the general condition of the body. It is of importance for the proper understanding of fever to determine the influence of heat upon the structure and functions of the various organs. To what extent can the febrile disorders of respiration, of circulation, of secretion, of nutrition, of innervation, be attributed directly to the elevated temperature? These are questions which can be answered better by experimental methods than by clinical observations, for the latter has to deal with the effects of heat, complicated by other circumstances whose influence cannot be accurately determined. The one method, however, should be made to control the other.

The most striking immediate effect of heat upon an animal is increased frequency of respiration. When a dog or a rabbit is placed in an atmosphere of 100° F. (37.8° C.), it at once begins to pant, and the respirations may run up to 150 or more. The causation of this increased respiration, to which the name heat-dyspnœa has been applied by Ackermann,[1] has been repeatedly investigated. Goldstein,[2] in Fick's laboratory, found that by applying to the carotid arteries tubes through which hot water is flowing, the respiration may be greatly increased in frequency. Goldstein's experiment is usually cited as the crucial one, showing that the increased breathing is due to the effect of the heated blood upon the respiratory centres in the medulla oblongata. Sihler,[3] working in the Biological Laboratory of the Johns Hopkins University, however, has demonstrated that the increased respiration of an animal exposed to heat is due to two causes, warmed blood and stimulation of the skin by the heat, and that probably skin stimulation is the more important factor. Some of Sihler's criticisms of Goldstein's experiments have been met by Gad and Von Mertschinsky,[1] who have made it evident that increased temperature of the blood stimulates the respiratory centres or increases their irritability. Section of the vagi does not check heat dyspnœa, so that this does not result primarily from the action of the increased temperature upon the terminal pulmonary expansion of these nerves. The removal of afferent impulses from the skin by section of the spinal cord does, however, exert so marked an influence that it cannot be doubted that heat stimulation of the skin is an important element in the causation. I have convinced myself of the correctness of Sihler's explanation by observing that in the hot box at temperatures of 90°–95° F. (32.0°–35° C.) rabbits often preserve their normal temperature and still their breathing is markedly increased, and that, on the other hand, upon taking them out of the box the respirations may sink before the internal temperature begins to fall. In one striking experiment the respirations fell immediately to about normal upon removing from the hot box a rabbit whose skull had been trephined on each side of the median line and the optic thalami punctured with a needle.

We cannot transfer directly to human beings the results of experiments on heat dyspnœa in animals, because in the latter respiration has a far more important function in temperature regulation than in the former. To keep cool, a dog pants under circumstances when a man sweats. As heat regulation is largely influenced by the cutaneous temperature, it is not improbable that in man heat stimulation of the skin is less prominent than the warmed blood acting upon the respiratory centres in increasing the frequency of respiration in fever.

Inasmuch as disturbances of the heart and of the circulation in general are among the most important symptoms of fever, it is natural that much attention should have been given to the study of the effects of heat upon the organs of circulation. The supposed injurious effects of prolonged high temperatures in fever have been usually attributed especially to some toxic action of heat upon the heart.

That the pulse-rate is quickened by artificially heating rabbits and dogs has long been known. The positive demonstration that this acceleration is due to the direct action of the heated blood upon the mammalian heart itself was first given by my colleague, Professor Martin.[2] By conducting through the dog's heart, isolated physiologically by the ingenious method which he devised, Martin proved that the heart "beats quicker when supplied with warm blood, and slower when cold blood is supplied to it; also, that the rate of beat depends much more upon the temperature of the blood in the coronary arteries than on its temperature in the right auricle or ventricle." These experiments make it unnecessary to recur to any action of the heated blood upon extrinsic cardiac nerves, or nerve-centres, in order to explain the quickened pulse of fever. Moreover, Fick[3] found that the nervous centres of the heart and blood-vessels are unaffected by heating the blood flowing through the carotid arteries in the manner adopted by Goldstein in his experiments on heat dyspnœa.

Professor Martin has kindly permitted me, in this connection, to mention certain unpublished results of experiments which he is now conducting upon the effects of heat and cold on the isolated heart. As these results are pertinent to our subject I gladly avail myself of this privilege. The table of an experiment which I have examined shows that the isolated cat's heart beats regularly, and more and more rapidly, as the temperature of the blood is gradually raised to 111.2° F. (44° C.). At this point the beats become irregular, but are restored to their normal rhythm by feeding the heart with cooler blood. The temperature of about 111° F. (43.9° C.) appears to be a critical one for the isolated heart. Above 111.2°–113° F. (44°–45° C.) the pulsations become slower instead of quicker as the temperature is raised. At 122° F. (50° C.) the heart's action ceased, but it was made to beat again by supplying it with cooler blood, showing that the cessation was not due to heat rigor. This interesting experiment teaches, among other things, that very high temperatures may produce results differing not only in degree, but also in kind, from those of temperatures only a degree or two lower.

We may consider it, then, established that increased frequency of the pulse in fever is referable to the direct action of the warmer blood on the nervo-muscular substance of the heart itself. Clinical observation of cases of fever makes it evident that there may be, and often are, present other circumstances which influence the rapidity of the heart's pulsations, circumstances which in themselves may slow or may quicken the pulse. Large series of statistics, therefore, are required to bring out the ratio between the pulse-rate and the temperature in fever, and even then for any given temperature the maximum and the minimum pulse-rates lie so far apart that the statement of the average increase in the frequency of the pulse for each degree of rise of temperature, such as has been computed by Liebermeister, has very little value.

Not only is the pulse-rate quickened in fever, but there are often other and more serious circulatory disturbances. In the fever produced in rabbits by injection of the swine plague bacillus, I find a reduction of the blood-pressure measured in the carotid artery, and others have obtained similar results in the artificial fevers of animals. The determination of the blood-pressure in fevers of human beings by means of Basch's sphygmomanometer has given in the hands of different experimenters such contradictory results that no conclusion can be drawn, unless it be the very probable one that the blood-pressure varies, being sometimes high, sometimes low, and sometimes normal in fever. That the arterial tension is often reduced is made evident by the marked dicrotism of the pulse-wave. This dicrotism, however, characterizes particularly septic and typhoid types of fever, and is absent during the chill of intermittent fever, and often in exanthematous and some other fevers, so that we cannot consider the blood-pressure and arterial tension as having any such definite relation to fever as does the pulse-rate.

It has been observed by Paschutin, Senator, and Mendelson[1] that the blood-pressure rises with increasing bodily temperature produced by exposure to heat. Mendelson found that the pressure begins to sink as the temperature approaches a point incompatible with life. In these experiments the animals were subjected to rapid elevations of temperature. I find that when a rabbit is gradually and cautiously heated in the hot box used in my experiments, the rise of temperature is less marked and may not surpass, even for temperatures of 107° F. (41.7° C.), the normal limits of variation which may be found in the blood-pressure of the same animal examined at different times. These measurements, however, are not very conclusive, for, as has been already remarked, rabbits which have been operated upon do not stand well artificial heating.

I have observed that the rhythmical contractions of the blood-vessels of the rabbit's ear are feeble or absent when the temperature is much elevated by artificial heating, whereas it will be remembered that in experimental septic fever these contractions are irregular and exaggerated.

Upon the whole, I think that we are justified in concluding that the variations of arterial tension in fever are much less dependent upon increased temperature than upon other factors, such as infection.

But the corner-stone of the doctrine which teaches that a chief source of danger in fever is the elevation of temperature is not the effect of increased temperature upon the pulse-rate or the arterial pressure, but is the belief that prolonged high temperature exerts a directly paralyzing influence upon the heart. The main support of this belief is not the admitted fact that extremely high temperatures paralyze the heart, for these critical temperatures lie far above the ordinary high temperatures of fever and in a region where all admit the dangers of the excessive internal heat. The stately superstructure has been built up chiefly on the basis of experiments showing that when the internal temperature of animals has been maintained for some time at a high point by exposure to external heat, parenchymatous or fatty degeneration of the heart-muscle ensues. It is true that all experiments are not in accord upon this point, and that, as a rule, pathological anatomists have not given adherence to the doctrine that parenchymatous degenerations are chiefly dependent upon high temperature; still, this doctrine has gained a wide acceptance among clinical men, and is advocated with especial force by Liebermeister. I have, therefore, thought it desirable in my experiments to give especial attention to this question.

Among previous experimenters on artificial heating of animals, Iwaschkewitsch, Wickham, Legg, and Litten may be mentioned as finding parenchymatous or fatty degeneration of the heart, liver, kidneys, and Walther, Obeynier, and Naunyn, as obtaining only negative results. It is not necessary here to enter into a criticism of these different experiments, which are of very unequal value. Litten's[1] experiments on the one side, and Naunyn's[2] on the other, appear to be the most carefully conducted. Litten, whose experiments are those usually cited, kept guinea-pigs in a double-walled metallic box which was at a constant temperature of 98.8° F. (37° C.) with dry air, or of 96.6° F. (36° C.) with moist air. He never failed to find fatty degeneration at the end of thirty-six to forty-eight hours. The liver was first affected, and then the heart and kidneys, which became fatty by the second or third day. The animals did not survive longer than five or six days, and by that time the fatty degenerations had reached an extreme degree. Von Recklinghausen[3] urges, with apparent justice, against these experiments, that the enforced inactivity of the muscles and the imperfect ventilation may have had as much to do in causing the degenerations as had the high temperature. These objections find support in the experiments of Naunyn, who, making use of a much larger and better ventilating heating-box than Litten, failed to find any parenchymatous or fatty degeneration in his rabbits after they had been exposed for two weeks to higher temperatures than Litten employed.

As my experiments confirmed in other respects Naunyn's results, I was quite unprepared to find that my rabbits, after a variable period of artificial heating, quite constantly presented fatty degeneration of the heart, liver, and kidneys, and sometimes of the diaphragmatic and intercostal muscles. I never found the degeneration at so early a period as did Litten. It was not until the rabbit had been kept for at least a week with an average rectal temperature of 106° F. (41.1° C.), that the degeneration was noticed, and then only in moderate degree. The higher and the less fluctuating the internal temperature, the more certain was the degeneration to appear. I could reckon upon obtaining rabbits with well-marked fatty degeneration of the heart by keeping them for ten days with a rectal temperature between 107° and 108.° F. (41.7° and 42.2° C.). I am not prepared to account for the discrepancy in this respect between Naunyn's and my experiments. The box used was larger than that employed by him, and every care was taken to keep it well ventilated by leaving at least one-third, and often one-half, of the top open.

I do not think that my experiments altogether do away with the force of Von Recklinghausen's criticisms. The fact that, in these experiments, the degeneration made its appearance at the end of a week or ten days, and in Litten's in forty-eight hours, to say nothing of Wickham Legg finding it at the end of twelve hours, would suggest that if the rabbits were heated in a still larger and better ventilated apartment the degeneration might not occur at all, or might be deferred to a much later period. In my opinion, however, even if full allowance be made for this line of argument, we must still admit that prolonged high temperature is an important factor in the causation of fatty degeneration.

That it is not the sole factor, no one can doubt. As is well known, fatty degeneration is produced by anæmia and by a variety of poisons, and even in fevers most pathologists are convinced that it bears a closer relation to the kind and the degree of infection than it does to the height of the temperature. It is more frequently absent than present in pneumonia, even where there have been symptoms of heart failure.

The kind of degeneration present in my rabbits was fatty, and not parenchymatous. Probably all who make many post-mortem examinations will agree with Von Recklinghausen that altogether too liberal use has been made of the diagnosis of parenchymatous degeneration, and not sufficient account has been taken of the anatomical changes of the parenchyma produced by post-mortem chemical changes, such as acid formation, etc.

In order to determine what influence is exerted by infection, combined with high temperature, I inoculated a rabbit, which had been in the hot box for four days, with the bacilli of swine plague. These bacilli, if not identical with, are closely allied to, those of rabbit septicæmia, and are extraordinarily virulent for rabbits. In thirty-six hours the animal, which had remained at a high temperature in the box, was dead, and the most extreme fatty degeneration of the heart and other organs was found. As in other experiments the degeneration had not made its appearance at this early date, there can be no doubt that the infection was an important element in the causation. That it received powerful support in the high temperature, however, is proven by the fact that little or no degeneration of the heart is observed, after infection with this organism, when the animal is kept at ordinary temperature.

Admitting, then, that the high temperature aids in the causation of fatty degeneration of the heart in fever, the question arises: What do we know of the effects of this degeneration upon the functions of the heart? I will say nothing of the growing tendency to transfer a large part of the classical symptomatology of Quain's fatty heart to other conditions, particularly to disease of the coronary arteries and chronic myocarditis; we are concerned at present only with the occurrence of this degeneration in fever. Have we not been somewhat hasty in assigning to degenerations of the heart-muscle so large a share in the production of heart-failure in fevers? One cannot look at a muscular fibre in which the striated substance is all replaced by fatty globules, and suppose that its functional activity was unimpaired; but into what serious errors should we fall if we attempted to deduce from the anatomical changes in the liver-cells, or the renal epithelium, the corresponding functional disturbances? Certain it is that symptoms which are usually considered those of heart failure are often enough present in fevers without finding at the autopsy any degeneration of the heart, and, on the other hand, such degeneration may be discovered without any history of these symptoms, although, of course, the two are often associated.

In the face of these doubts it seemed desirable to determine, if possible, experimentally, the damage inflicted upon the cardiac functions by the presence of fatty degeneration of the heart-muscle. That this degeneration may exist without apparent injury is rendered probable by the fact that a rabbit which has been kept for three weeks in the hot box, at a high temperature, and in which there is every reason to suppose that fatty degeneration has occurred, may present no symptoms of heart paralysis, and when removed from the box appear and remain perfectly normal. An instance has already been mentioned where one rabbit, at the end of three weeks, was killed and presented marked fatty degeneration of the heart, and another, which had possessed a higher average rectal temperature, was removed from the box at the end of the same period, and appeared for ten days perfectly normal, when it was used for another purpose. That this degeneration can be recovered from is, moreover, rendered probable by clinical experience, and is universally admitted.

[2] Naunyn: Op. cit.

[3] Von Recklinghausen: Handb. d. Allg. Pathologie d. Kleislaufs u. d. Ernährung, p. 512. Stuttgart, 1883.

Once, in teasing out a bit of fatty-heart muscle from one of the rabbits, I made a curious observation. Near the edge of the cover-glass, where there was a slight current in the physiological salt-solution, rhythmical contraction was observed in a group of muscle-fibres. This interesting spectacle could be watched under the microscope for ten minutes. These contracting fibres were filled with fatty globules, and only here and there, and then indistinctly, could any trace of striation be detected. This observation teaches that a fatty degenerated muscular fibre is capable of contraction, but, of course, warrants no further conclusions.

Far more important than any inferences which can be drawn from such observations is the measurement of the actual blood-pressure in animals whose hearts have undergone fatty degeneration. This I have done in three instances. The rabbit was removed from the box at the end of ten days to two weeks, and the pressure in the carotid artery was measured by a mercury manometer attached to Ludwig's kymograph. In no instance was the blood-pressure found to be lower than that normally present in rabbits. In an experiment recently performed the average pressure was 125 mm. of mercury; the pulsations were regular; the heart responded to stimulation of the vagi in an entirely normal manner. After such stimulation the pressure in one case rose to 176 mm. of mercury. Immediately after the measurement of the blood-pressure the rabbit, as in the previous instances, was killed, and marked fatty degeneration of the muscular fibres was found. In many of the fibres the striation could not be made out, and only fatty globules were visible; in others, which also contained fatty granules, the striation was distinct. The degeneration involved the whole muscular structure of the heart. A similar appearance in a human heart would be considered to indicate well-marked fatty degeneration.

These experiments show that a rabbit's heart which has undergone marked fatty degeneration from exposure to heat may perform its functions, to all appearances and for the time being, in a perfectly normal manner. There is at least one consideration which should make us cautious in drawing far-reaching conclusions from these experiments. There are diseases of the heart—I need only refer to lesions of the coronary arteries—in which the functions of the organ are performed for a longer or shorter time, apparently in a perfectly normal way, and then heart-failure suddenly appears. It is probable that here, too, the blood-pressure would be found normal at a certain period of the disease, and still it would be an error to suppose that the lesion does not damage the heart. Whatever force there may be in this analogy, I still think that these experiments, as well as careful pathological and clinical observations, necessitate some revision of the current opinions concerning the significance of fatty degeneration of the heart in fever.

So much time has been devoted to a consideration of the effects of heat upon the respiration and the heart, that the limits of the present lecture will permit hardly more than a summary of the effects exerted by heat upon other functions and organs of the body. On account of the great clinical importance of the subject it seemed desirable to treat with especial fulness the influence of increased temperature on the heart.

What part has increased temperature in producing febrile consumption of tissue? In the first lecture mention was made of Pflüger's experiments, showing that animals with elevated temperature, produced by exposure to heat, absorb more oxygen and excrete more carbonic acid than at the normal temperature. This is in conformity with the general law that within certain limits cell activity is more energetic at high than at low temperatures. It was also shown in the first lecture that only a comparatively small part of the increased oxygen absorption, and carbonic-acid elimination, in fever, can be referred to the immediate effects of high temperature. It has not been demonstrated that the respiratory gases in human beings are increased by artificial elevation of temperature. Indeed Voit[1] was unable to find any such effect of increased temperature in human beings on the respiratory gases as both he and Pflüger observed in animals.

Inasmuch as increased disintegration of nitrogenous material is such a prominent disorder in fever, much attention has naturally been given to determining how far this can be explained by elevated temperature. That it cannot all be so explained is proven by the interesting observation of Sydney Ringer, that excessive elimination of urea antedates the rise of temperature in intermittent fever, and Naunyn has found the same to be true of the septic fever of dogs.

The experiments which have been made to determine the influence of artificial heating on the amount of urea excreted by man and by animals have yielded contradictory results. A number of these experiments are of little or no value, because no attention was given to establishing beforehand nitrogen equilibrium. Schleich's[2] experiments may be mentioned as perhaps the most accurate of those showing an increase in the urea excreted under the influence of exposure to heat. The more recent experiments of Simanowsky[3] were made in Voit's laboratory, with especial precautions as to the establishment of nitrogen equilibrium. He failed to find any increase in the excretion of urea, as the result of exposure to external heat. While, then, this question must be left at present *sub judice*, there can be no doubt that only a part, at least, of the excessive disintegration of nitrogenous substance in fever can be assigned to the influence of the increased temperature.

The loss of weight exhibited by animals kept for a long time in a hot atmosphere is usually explained by the excessive evaporation of water from the body. In many of my experiments the rabbits were freely supplied with food and water, and still the loss of weight was very noticeable. I am inclined, therefore, to attribute to the increased temperature under these conditions a decided influence upon the consumption of tissue.

Senator[4] found the urine of rabbits artificially heated to contain more albumen than is found occasionally in the urine of healthy rabbits. This observation I have not been able to confirm on the rabbits in my experiments, and probably this difference is to be explained by the more rapid and intense heating employed in Senator's experiments. Senator explains the heat albuminuria by the rise of arterial pressure on the renal vessels, but this is not in conformity with the interesting experiments of Mendelson,[5] who found, by means of Roy's oncometer, that both in thermic and in septic fevers of dogs the kidney is anæmic, while the general blood-pressure is elevated.

No satisfactory explanation has yet been offered of the diminution of perspiration which distinguishes fever so strikingly from the condition produced by exposure to high external temperatures. Luchsinger's assertion that this is the result of lessened irritability of the sweat-centres in the spinal cord remains to be proven, and at the best is not a satisfying explanation.

[4] Senator: Du Bois-Reymond's Archiv, 1883, Supplement Band.

[5] Mendelson: Op. cit.

Bokai,[1] in a recent experimental research on intestinal peristalsis in thermic and septic fevers, comes to the conclusion that the constipation of fever is to be explained by the heated blood stimulating the nerves inhibiting intestinal peristalsis. If this should be confirmed, then it would be proven that at least three symptoms of fever, the quickened respiration and pulse, and the constipation, are direct effects of elevated temperature.

When we consider the important nutritive changes in the muscles accompanying increased thermogenesis we shall be inclined to attribute to these alterations and the associated abnormal innervation, rather than to increased temperature, the muscular pains and weakness which form such an early and frequent complaint in many fevers.

The investigations hitherto published of changes in the blood, produced by increased temperature within febrile limits, are not of sufficiently definite and satisfactory nature to warrant any consideration on the present occasion.

Nor am I acquainted with any positive experimental evidence (save Bokai's work already mentioned) that increased temperature is concerned in the production of the digestive disorders of fever. It has already been said that the rabbits with high internal temperatures in the hot box ate greedily, but these voracious animals cannot be considered favorable subjects to test this question.

Especial emphasis has been laid by Liebermeister, and those who accept his teachings, upon the dependence of the nervous symptoms of fever, particularly the so-called typhoid symptoms, on the elevation of temperature. There is, however, abundant clinical evidence to disprove this doctrine. Reference need be made only to relapsing fever, and especially to the aseptic fever described by Genzmer and Volkmann, in which there is entire absence of the whole group of so-called nervous symptoms. Moreover, Liebermeister's opinion in this respect is not supported by adequate experimental evidence. Unless the temperature of the brain or of the entire animal be brusquely raised to a high point by coarse methods, no disturbance of the cerebral functions is noticed until the temperature reaches a critical point, beyond which further increase is likely to prove rapidly fatal. At this critical point the animal, which before has lain quietly, becomes very uneasy, and if the temperature rises higher it has convulsions and coma, and dies.

I have endeavored to bring before you in this lecture the experimental evidence relating to the effects of increased temperature upon the general condition of the body and upon the functions of its various organs. I have given account, as briefly as possible, of some experiments which perhaps shed additional light upon this important subject. In the course of this lecture emphasis has repeatedly been laid upon the necessity of controlling the results of the experimental method by clinical observation, and here and there I have endeavored to institute this control. Further than this I shall not attempt to set before you the clinical evidence regarding the effects of increased temperature in fever. There are those here more competent than I to deal with this side of the question. We may feel assured that when all the facts are before us, and are properly interpreted, there can be no lack of harmony between the results of experimental and those of clinical investigations.

PERNICIOUS ANÆMIA:

CERTAIN QUESTIONS SUGGESTED BY CASES AND AUTOPSIES.[1]

BY J. WEST ROOSEVELT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, IN THE MEDICAL COLLEGE OF THE WOMAN'S INFIRMARY, OF NEW YORK; VISITING PHYSICIAN TO BELLEVUE AND ROOSEVELT HOSPITALS.

FROM the study of certain cases of pernicious anæmia which came under my own treatment, or which I was enabled to observe through the courtesy of my colleagues at Roosevelt Hospital, and from reading various reported cases, I was led to the following conclusions: First, that in some cases of pernicious anæmia there is found a lesion of important organs not directly concerned in blood making, which possibly may have produced the blood disease. Second, that after these cases, together with those which seem to be caused by intestinal parasites and those which follow hemorrhage, have been excluded, there remain some in which the blood-lesion seems to be primary.

Let me first ask your attention to the following histories (in which, I regret to say, many important facts are wanting), and let me ask your opinion in regard to the truth of the above propositions.

CASE. I.—Catharine J——, aged twenty, single, domestic, Irish. Admitted February 24, 1887. Family history unknown. Parents both dead, cause unknown.

No history of venereal disease, rheumatism, serious cough, or hæmoptysis. Before the present illness she never had suffered from dyspnœa, vomiting, or œdema; was always temperate. She had measles and scarlatina when a child. She has frequently suffered from headache. Menstruation began at sixteen and was regular until one year ago. She has never eaten much meat, and has always had a fondness for pickles and tea, eating handfuls of the leaves of the latter. Her friends say that she has always had a pale yellowish complexion.

For the past year her menstruation has been irregular, appearing for the last time four months ago. She dates her illness from the time of the last period.

She suffered from headache, anorexia, and weakness. The headache was frontal, and the pain dull. It was not constant. She also suffered from vertigo and saw muscæ volitantes. She has vomited only twice. Two months ago she noticed that she was getting paler and more yellow in color, and since then has had occasional œdema of the feet. One month ago she had a sharp attack of localized pain in the right hypochondrium, followed by jaundice, and preceded by a chill. Pain lasted about fifteen minutes. Similar attack two weeks ago, and again one week ago. For a month has suffered from dyspnœa on exertion. She thinks her urine has been diminished during the last two months. Her color has become much worse of late. During her illness she has taken no proper food, but has lived on articles like charlotte russe, ham, tea-leaves, sarsaparilla, etc.

On Admission.—Fairly nourished. Pale and slightly jaundiced. Sclerotics yellow. Mucous membranes pale. Large cicatrix on right side of face, smaller one on left cheek, and others on neck and right breast, the results of a burn received when a child. Tongue very pale, clean, moist. Appetite poor. Constipated. Pulse fairly strong, regular, 104; respiration 26; temperature 99.4°. Urine amber, clear, neutral; specific gravity 1.016, no albumen; microscopic examination negative. Lungs normal. Anæmic murmur over heart. Venous hum in neck. Examination of blood shows 1,500,000 red disks to the c.mm.

March 7th.—Ophthalmoscope showed no hemorrhages in fundus.

March 10th.—Still jaundiced. Has severe headache.

March 18th.—Has had a better appetite, and has sat up during the last few days. Color no better. To-day red disks number about 1,100,000. The disks are of irregular size and shape. Some are large, about twelve to fourteen millimetres in diameter. Some are very small. Many are observed pear- and kidney-shaped. The white cells are relatively to the red, but not absolutely increased.

---

[1] Bokai: Archiv f. exp. Path. u. Pharm., Bd. xxiii.

[1] Read before the Section on the Practice of Medicine of the Academy of Medicine of New York, March 20, 1888.

The patient improved in appetite, strength, and color for a time. Headache was no longer observed. No hemorrhages had yet appeared in the retinæ.

April 4th.—Red disks number 1,390,000.

April 16th.—Felt worse; appetite lost.

April 19th.—Red disks, 1,300,000.

April 26th.—Nausea is present. After this she was much troubled with headache, nausea, and vomiting, and became very weak. Grew sometimes a little better, but on the whole lost ground pretty steadily during the month of May.

June 8th.—Punctate and flame-shaped hemorrhages were observed in both retinæ.

June 9th.—Hæmoglobin twenty per cent. of the normal.

No further examination of the blood is recorded. The patient sank and died on June 28th, at 9.30 P.M.

During the illness her temperature ran between 99° and 100.6°. On June 3d it reached 102.4°, P.M., falling again the next day to the average. The pulse was pretty constantly about 100. It occasionally rose to 120. The respirations numbered from 24 to 30. The evening temperature was usually from ½° to 1° higher than the morning. Just before her death the temperature rose to 101.4°.

The treatment was with arsenic, oxygen, and iron, and various remedies to relieve the vomiting and constipation, as occasion required.

Autopsy, June 29, 1887, at 1.15 P.M., showed the body to be poorly nourished. Rigor mortis fairly marked. The skin and all the organs were slightly jaundiced. The blood was pale. The spleen measured 2 by 7 by 2½ inches, and was slightly waxy in appearance. The liver was rather firm. Three small facetted calculi, composed of inspissated bile, were found in the gall-bladder. Every organ examined, save those noted above, was absolutely normal but jaundiced. The brain was not examined. There were no enlarged lymphatics. It is to be regretted that no note was made of the condition of the marrow. The stomach was the only organ submitted to careful microscopical examination, and it was absolutely normal.

We have, in this case, a girl who had indulged in a bad diet, and who was at the age when simple anæmia is common. For a year she had had irregular menstruation, but dated the real beginning of her illness from the period at which menstruation ceased—four months before admission. It is common for women thus to date illness from the time of suppression of the menstruation. Two months before admission she observed that she was paler than before, and she had occasional œdema of the feet. She does not seem to have been really ill, however, until after the attack of jaundice, one month before she was first seen. Following this, and two similar attacks, we note the graver symptoms. Although she had temporary improvements, she finally died, having presented the usual symptoms of pernicious anæmia. From the autopsy, I think we may assume that the jaundice was the result of inflammation of the bile-ducts, produced by the calculi found in the gall-bladder. According to the patient's own statement, the disease terminated fatally about eight months after its onset (dating as she dated it, from the cessation of menstruation, four months before admission). As menstruation had been irregular for a year, it is probable that she suffered from anæmia at least as long as that before her admission. Taking into account the patient's age and her diet, it seems to the writer that it is possible that the disorder began as a simple anæmia, but that the attack of jaundice still further increased the anæmia. It is known that jaundice can produce pretty intense anæmia of itself. As a result of the jaundice, the blood-forming organs were taxed beyond their powers. The increasing anæmia still further crippled them, and the "vicious circle" thus established led to the patient's death. Jaundice has been noted in several cases.[1]

In Case II. we have a very different story. We find a history of chronic gastritis extending over six months at least. Emaciation is a prominent symptom. In spite of the emaciation the case resembled very closely pernicious anæmia. Her color was very peculiar and characteristic.

Nellie H. W——, aged fifty-four, single, Ireland. Bookbinder. Admitted May 24, 1887. Family history negative. No history of venereal disease or alcoholism. Never had rheumatism. Has had dyspnœa on exertion since she was twenty years of age. Her feet and legs have swollen at times during the past ten years. During the last three or four years has suffered from palpitation of the heart. First menstruated at fifteen. Save that the catamenia occurred about every three weeks, her menstrual life was normal and the menopause was reached, without special discomfort, at the age of forty-one.

In 1864 was troubled with bleeding piles and lost a great deal of blood. Under treatment at the New York Hospital was cured. During this same year she suffered from chilly feeling, followed by fever and sweating, the attacks occurring in the morning. Under treatment these attacks subsided, but they have recurred at intervals since.

During the last six months has suffered from weakness, loss of appetite, epigastric pain, and flatulence. She has vomited seldom, but says that a month ago she vomited some dark blood. Since the beginning of her illness she has grown yellowish-white in color.

Condition on Admission, May 24, 1887.—Much emaciated. Peculiar yellowish-white color of skin, looking very like that seen in the cancerous cachexia. Mucous membranes pale. Tongue pale, clean, and moist. Appetite poor. Constipated. Some pain in micturition. Pulse compressible, 100. Respiration, 32. Temperature, 99.2° (A.M.). Urine acid, pale, cloudy, specific gravity, 1.012. No albumen. Microscopic examination: Epithelium, leucocytes, bacteria, granular matter.

Physical examination at this time records normal chest. She suffered from vomiting and from sweating at night, and feeling chilly in the morning. Constipated.

June 6th.—Blowing systolic murmur heard, loudest at third space to the left of the sternum and transmitted up vessels of neck. Heart not enlarged.

There is some tenderness in the epigastric region. The belly is shrunken. No tumor felt. Blood-disks number 1,600,000 to the c.mm. Hæmoglobin, thirty per cent.

After this the patient seemed to remain for a long time in about the same condition. Punctate and flame-shaped hemorrhages were observed in the retinæ. The red cells were found to be of very varied size and shape. The temperature until July 16th ran between 99° and 100°. The pulse remained about 100. July 16th: A.M., pulse, 100, temperature, 99.8°; P.M., pulse, 100, temperature, 100.6°. July 17th: A.M., pulse, 100, temperature, 101.4°; P.M., pulse, 100, temperature, 101.6°. The patient during these days was sinking rapidly. There was no increase in the respiration, no cough. On July 18th, at 12.30 P.M., she died.

Autopsy, two hours after death. The body was emaciated and poorly nourished. Blood very watery. Brain not examined. Left lung normal, a few old pleural adhesions. Right completely adherent. Lower lobe in condition of gray hepatization. Heart small, very slight thickening of mitral valve, otherwise normal. Liver and spleen normal. Suprarenal bodies look congested. Kidneys: left normal size and normal in appearance, save that there were a few small cysts in it, and that there were some hemorrhagic streaks in the pyramids and the cortical markings were lost. In place of right kidney is a mass of fibrous tissue. Stomach much contracted. Mucous membrane pale and looks finely mammillated. Œsophagus normal. Large and small intestines diminished in calibre, otherwise normal. Uterus and ovaries atrophic.

---

[1] See Quinke: Volkmann's Sammlung Klin. Vort., No. 100; also Bartels: Berlin. Klin. Wochenschrift, 1888, No. 3. The symptom is also noted by others.

The stomach, microscopically examined, showed everywhere the mucous membrane much thinned. Around the cardia the muscular layer was thickened. The muscularis mucosa was normal. There was atrophy of the gastric tubules everywhere. The interstitial connective tissue was increased in amount. The arteries were in many places thickened by endarteritis. The most marked lesion was infiltration of the stroma of the mucosa with round cells.

The kidneys showed areas in which the tubules and tufts were destroyed by new connective tissue. There was also pretty extensive cloudy swelling of the epithelium of the convoluted tubes. The vessels were not, as far as could be ascertained, diseased.

In this case we have the lesions of chronic gastritis; there is pneumonia. The state of the only remaining kidney is such as to leave us in doubt as to whether the lesions were only the natural increase of fibrous tissue found usually in patients of her age, to which have been added a parenchymatous degeneration due perhaps to the pneumonia, or whether the case is one of true chronic diffuse nephritis. The absence of change in the renal vessels is against the latter view. The stomach lesion is the same, after all, as that observed in many cases of chronic gastritis. There is an increase of intertubular tissue, and an infiltration of it with indifferent cells; there is an increase of the adenoid tissue normally found in the stomach, and atrophy and degeneration of the glandular epithelium, and there is endarteritis. Of the relation between the stomach lesion and the symptoms, this much alone can be said: Many patients live a good while, and pretty comfortably, with stomachs as bad as this one. When this patient became very ill, she presented symptoms rationally explicable by the blood state. It is possible that the blood state may have been secondary to the stomach lesion, or may have produced it; may simply have occurred as an accompaniment in no way connected with it, or the anæmia and the gastritis may have reacted badly upon one another. It hardly seems likely that the stomach lesion was really secondary to the blood change. Such a relationship would be hard to explain. On the other hand, anæmia of a fatal kind, secondary to gastritis alone, is perfectly conceivable; but it seems to me that we must admit, for the production of pernicious anæmia as the result of gastritis, the necessity either of independent disease of the blood-forming organs, or that, as a result of the stomach lesion, such a change takes place in the gastric ferments as to lead to the production of poisonous digestive products, instead of normal peptones. The cases recently reported, cured by washing the stomach, confirm the possibility of this digestive error. Granted the existence of gastritis and the blood lesion, and the bad effects of one lesion on the other are perfectly comprehensible. Evidence that the stomach and blood lesions were both the result of the same cause is, in my case, wanting. The exact relation of the kidney lesion to the case is of course uncertain. I doubt if the kidney is really to be considered as diseased.

It is interesting to note that in a number of cases symptoms of dyspepsia have preceded the anæmia. Nothnagel records a case with "cirrhotic contraction of the stomach."[1] Henry and Osler record one where, after long-continued symptoms of gastric disease, fatal anæmia occurred.[2] Kinnicutt describes two cases with stomach lesions.[3] Fenwick also mentions some, but his article is not very satisfactory.[4] Brabazon also records stomach lesions.[5] It is difficult to understand, from the printed descriptions, exactly in what the cases of Henry and Osler and of Kinnicutt differ from chronic gastritis, though these authors seem to see some difference. It is unfortunate that the autopsies in the latter's cases were made so long after death, as an entire absence of gastric tubules is to be regarded as among the possible post-mortem changes.

Case III.—James McF——, aged thirty-three; clerk. Admitted March 11, 1880.

Family history good. Frequent mild attacks of rheumatism. Syphilis two years before admission. Very hard drinker.

Three weeks before admission was in usual health. Then a painful swelling, which subsided in a day or two, appeared in his neck under the lower jaw. From this time he lost appetite, and suffered from vomiting, regurgitation of yellowish fluid, dull pain in abdomen, some dyspnœa and palpitation, and increasing weakness. During past two weeks has had frequent desire to micturate. Bleeding from the socket of a right molar tooth, and from a prolapsed rectum (which latter has existed a long time, but which has been neglected during illness) troubled the patient for the last two days. Patient has probably long been pale, since neither he nor his friends have noticed much change in his color of late. Mental condition unchanged until yesterday, when his friends think he was delirious for a while. During last two years has lost flesh. Headache has seldom occurred during his life.

On admission.—Yellowish skin, fetid urinous odor of breath; very weak. Stupid, but talks rationally. Expressionless face; brown, bloody tongue. Poor appetite; constipated now and since attack began. Pulse weak, 102; respiration, 20; temperature, 97.8°. Urine, acid, sp. gr. 1.015; albumen, five per cent. Heart and lungs seem normal. Oozing from gums and rectum.

For two weeks the patient continued very ill. He passed a good deal of urine of low specific gravity, containing a little albumen.

The bleeding continued. Gradually the symptoms subsided, his color became better and less yellow. He then had the ordinary symptoms of Bright's disease. He was removed from the hospital March 14, 1881, in a dying condition, suffering from uræmia. He died shortly afterward, and no autopsy was held. The apparent duration of his illness was about thirteen months.

The case occurred before examination of the blood by exact instruments was often practised. The resemblance of the symptoms to cases of pernicious anæmia was marked during the earlier part of his sickness. The record is meagre, and the absence of an autopsy is to be regretted.

In Case IV. the history is more detailed. The patient, a negro, aged twenty-two, entered Roosevelt Hospital November 7, 1887. Occupation, expressman. Probably had syphilis (sore on penis and enlarged, non-suppurating inguinal glands) two months before admission. Measles, when a child, is the only acute disease known to patient. Temperate.

For past two years has occasionally suffered from palpitation of the heart, headache, œdema of feet and legs, and vomiting, and has sometimes seen *muscæ volitantes.* These are the only symptoms of Bright's disease which had existed. Eight days before admission, while in usual health and at work, was seized with vomiting of thin greenish fluid, weakness, headache, and feverishness. Next day vomited same material, but also, after each attack of vomiting, spat up two or three mouthfuls of dark fluid blood; vomiting then ceased, but continued to spit blood at times. Yesterday, a chill, lasting about an hour, followed by fever, lasting about two hours. From the onset has had anorexia and diarrhœa. No palpitation nor dyspnœa since attack began.

On admission.—Well nourished; sluggish mental state. Tongue thin, white coat, moist. Mucous membranes pale. No glandular enlargements. Lungs normal. Liver dulness from in nipple line from fourth space to free border of ribs. Heart apex fifth space, one-half inch inside nipple. Systolic murmur audible over whole præcordium, transmitted to the left, from the apex and up the vessels of the neck from the base. Diastolic murmur heard at base, and down sternum. Pulse of fair strength, 84; respiration, 14; temperature normal. Urine pale, slightly cloudy, neutral. Sp. gr. 1.010. Considerable albumen. Epithelium, granular matter, and mucus, and a few leucocytes. There is a slight white discharge from penis. After his admission, the patient continued weak. Vomiting did not occur. He had some hypogastric pain and some rectal pain, due to fissure in ano. On the twenty-fifth day of his disease, moderate bleeding occurred from the rectum. On the twenty-seventh day, bleeding from the mouth. The cheeks were swollen, but there was no solution of continuity. On the twenty-ninth day, hæmoglobin, thirty per cent. Red disks, 2,364,000 to c.mm., white normal proportion to red. A few pear-shaped and elliptical red disks. On the thirtieth day, he had become semi-comatose and the bleeding increased somewhat. On the morning of the thirty-first day, at 12.30, he died.

[3] Proc. of the Soc. of Amer. Phys., 1887.

[4] London Lancet, vol. ii., 1887.

[5] Archives Générales, January, 1884. Original not accessible to me.

Urine, frequently examined, was always about the same as on first examination. No casts were found. On and after the twenty-ninth day the urine was brown, and on the thirtieth day a few red cells and bacteria were observed in it. The temperature was normal.

Autopsy, fourteen and a half hours after death. Body well nourished. Blood watery. Liver and spleen somewhat enlarged, but otherwise normal. Stomach normal. Heart hypertrophy, with slight dilatation of left ventricle. Aortic valves a little thickened. Chordæ tendinæ of mitral shortened, valve thickened and somewhat insufficient; heart is not otherwise diseased. Kidneys normal size; capsule not adherent; surface nodular; cortex mottled red and gray.

(I am indebted to Dr. Delafield, under whose care the patient was, for the privilege of reporting it.)

It would seem that we have here a condition of "pernicious" anæmia complicating Bright's disease. The resemblance to the former case is striking. The former seemed to recover from his blood lesion, and die long afterward of his kidney disease; the latter died in thirty-one days from his blood lesion. He had nothing resembling uræmia. Of course, the occurrence of these symptoms during the course of Bright's is well known. The blood has not yet been sufficiently often examined, but the patients, in some cases of Bright's disease, seem to suffer from the same symptoms as those of pernicious anæmia, and in Case IV. the blood change was typical enough.

GENERAL DESCRIPTION.—It is needless to describe in detail the well-known symptoms. A short outline will suffice. The onset is usually gradual, sometimes acute, and pallor is frequently the first symptom noted. The pallor, when the disease is fairly advanced, is frequently rather characteristic. The face has not a dead-white hue, nor is there the fawn color so often seen in malignant disease. The sclerotics are not often bluish-white with the look like fine porcelain sometimes seen, especially in phthisis, simple anæmia, malignant disease, cirrhosis of the liver, and Bright's disease. There is seldom any puffy look. The skin, in many cases, has a yellowish, lustreless, white tint; the sclerotics look dirty yellowish-white. Dyspnœa and palpitation of the heart on exertion, syncope, increasing weakness, weariness, mental and physical headache, and sometimes other pains, as neuralgia and aching in the limbs and bones, loss of appetite, vomiting—these are the usual early symptoms. Sooner or later an irregular fever sets in; the power of sustained thought becomes weakened; there may be delirium; prostration is extreme. Perhaps some dropsy is developed. Emaciation is not common, patients usually retain their fat, or it may increase. Hemorrhages from various mucous membranes occur in some cases, and occasionally purpuric spots are seen in the skin. Hemorrhages into the choroid and retina are almost invariably present. Disturbances of vision are common. The red blood-disks and the hæmoglobin are below the normal. The reduction varies but may reach as low as one-sixth or one-seventh of the normal. The hæmoglobin may be reduced in the same ratio as the disks, or it may not reach such a low point. The white cells are nearly normal in number. The red cells show changes in size and shape, and it is said that nucleated disks sometimes appear.

The duration of the disease varies; some cases seem to terminate fatally within a few weeks or months, others may last for years. The course is not steady; temporary improvement followed by relapses is often seen. The prognosis is very grave, but, probably, some cases recover. The question of recovery is, of course, not to be considered if by "pernicious" we mean, as do some authors, a necessarily fatal disease.

Diagnosis.—The differential diagnosis of the pernicious from the simple form of anæmia is difficult, or, perhaps, impossible. There seems to be no symptom, nor group of symptoms, found in the grave disease which is not found in the milder type. Patients with simple anæmia may have the same blood lesion, the same fever, dyspnœa, palpitation, nausea, and vomiting, the same hemorrhages —in fact, all the symptoms of pernicious anæmia. Iron usually benefits or cures the simple form, and does not improve the pernicious one. The results of treatment may aid the diagnosis, but it is uncomfortable to think that we may let a patient with pernicious anæmia die while trying to find out whether the case is pernicious or not, by giving iron. Of course, if by the word "pernicious" we mean necessarily fatal anæmia, we may wait until recovery or death clears up the diagnosis. The age and sex of the patient should receive due weight in diagnosis, and a history of one of the known causes is of value. It seems to the writer that a diminution in the number of red disks much greater than the patient's symptoms would lead us to expect, or a much greater proportional diminution in the amount of hæmoglobin than in the number of disks are points in favor of simple anæmia. Diminution of hæmoglobin with a normal number of red disks is only seen in the simple form.

The resemblance of these cases to Addison's disease is quite marked, but in this disorder anæmia is not an essential symptom.

Whether or not the disorder is closely related to Hodgkin's disease and to leucocythæmia is not yet quite settled. Clinically, Hodgkin's disease is to be differentiated by the lymphatic, splenic, or hepatic enlargements, while the excess of white cells distinguishes leucocythæmia from the others.

Lesions.—The blood, as seen during life, is paler and thinner than normal. The red disks are much diminished in number. Perhaps fifteen or twenty per cent. of the usual number may be found. The disks are more or less altered in size and shape. Some are much smaller, some much larger, than the average in healthy blood. Many cells shaped like a pear, or tennis racquet, or kidney may be seen. Sometimes, it is said, nucleated red disks are seen. Although this latter statement is made by such good observers as to be indubitable, it must be remembered that an *appearance* resembling a nucleus is not rare in red disks, which seems to be the result of vacuolation or of some peculiar deposit of hæmoglobin near the edge of the disk, leaving a clear centre. The white cells, while often relatively, do not seem to be absolutely, increased in number. After death the blood presents the same appearance. It is said that the *quantity* of it is often reduced—a statement open to doubt. The hæmoglobin seems to escape soon after death, and stain the endocardium and vessels. Coagulation, both during life and after death, seems to take place slowly or not at all. Exact investigations of the plasma are wanting.

The marrow is sometimes diseased, sometimes normal. The spleen is generally normal. The liver is normal or occasionally fatty. Some enlargement of the lymphatics may occur. The thyroid gland has not been enlarged enough, so far as I can learn, to justify a statement as to its condition. The supra-renal capsules are unchanged. Doubtful lesions of these bodies have been described.[1]

The most common lesions seem to be fatty degeneration of the heart, liver, and kidneys. Similar degeneration of the great vessels is noted. The degeneration in the heart is either of the usual type, or, as described by Addison and others, zigzag lines of fatty degeneration are, in certain cases, observed. In a case observed by the writer, a seemingly typical pernicious anæmia was accompanied by general dilatation of the heart (case reported by Asta Burnegie in *New York Medical Journal*, vol. xlv., No. 1, 1887); no characteristic lesions of the brain or cord are found. Punctate hemorrhages in the former are mentioned by some observers. The semi-lunar ganglion of the sympathetic has been found seemingly diseased. Hemorrhagic extravasations into the retina and choroid are almost constantly found, together with some optic neuro-retinitis. Extravasations of blood elsewhere may occur. Inflammatory changes of any organ may occur as an incident of the disease. The serous cavities often contain an excess of fluid. Gastric lesions are seen in some cases. Chronic diffuse nephritis is observed in some. Lesions of the pancreas have been described. Certain intestinal parasites are sometimes seen. The body is usually fat. The muscles and all the organs are pale. The fat is often peculiarly yellow.

The *etiology* of the disorder is not clear. Bad food, foul air, overwork, and general bad hygienic conditions are found as possible factors in many cases; but if these causes in themselves were capable of producing the condition, it is likely that the disease would be very common, instead of rare. Pregnancy and the puerperal state, and especially repeated pregnancies, predispose to the affection. Güsserow records, among others, four cases in which the symptoms followed respectively a seventh, eighth, sixth, and tenth pregnancy. Pregnancy complicated by great anxiety and privation has preceded some cases. Prolonged lactation is sometimes noted. Disturbances of digestion existed for a long time before the onset in some. Rather chronic diarrhœa preceded others. In addition to these causes we have severe, or oft-repeated, or long-continued hemorrhages, or attacks of acute disease, antecedent to certain cases. Mental anguish and shock is suggested, by Wilks and others, as a possible occasional cause. Chronic bronchial catarrh, and various disorders with long-continued discharges of albuminous fluids, are noted.[2] Alcoholism seems to be a possible factor in the production of the condition. Syphilis is hardly to be mentioned as a cause. The occurrence of chronic nephritis, stomach lesions, and fatty liver has been recorded. Distinct history of recently true malarial infection has not been mentioned in the cases which I have studied. The general term, malaria, is too vague to be regarded. It covers too many diagnostic sins. The symptoms of the malarial cachexia differ in many respects from those met with in the disease under consideration.

Bacterial infection has yet to be shown to cause the disorder. In some cases certain parasites have been supposed to cause it. In regard to all of these, as, indeed, in regard to all the alleged causes, we must ask: Why are they so common and the disease so rare?

The case reported by Schapiro,[3] of cure of pernicious anæmia by the expulsion of a bothryocephalus latus, is interesting because, in addition to the worm, the boy suffered from constipation. The efforts to expel the worm incidentally relieved the constipation. When the bowels returned to a normal condition the patient recovered. It is hardly fair to blame the worm for all this. Surely the constipation played its part. The patient, it would seem, could not support both. Constipation can produce more or less anæmia, and perhaps it may have produced this case.[4]

As much time has been wasted by a misunderstanding of terms used by medical writers, I give the following definitions of certain terms used by me in this paper:

By the term "pernicious anæmia" I mean a *disorder having characteristic blood lesions, severe symptoms, and a marked tendency toward a fatal termination.* Although certain authors would exclude cases which recover, yet, for clinical reasons, with our present knowledge I think the above definition will suffice.

When speaking of cases of pernicious anæmia as "primary," I mean that in these cases, whatever be the cause, *the blood lesion is directly produced by the action of that cause, and not indirectly through disease of some organ not concerned in blood-making.* In "primary" cases we have this sequence: Cause, blood lesion. In "secondary" cases we have this: Cause producing lesion of some organ, lesion of this organ producing blood lesion.

I shall not discuss the question as to whether the blood change accounts for the symptoms. It is not worth while. Neither shall I consider the question whether the disorder results from diminished production or increased destruction of red disks, or both.

Looking at pernicious anæmia as I have defined it (making the definition broader than many will admit), may we not say, first:

That a condition with similar course and symptoms has been observed in cases with precedent grave stomach, kidney, and liver lesions.

Second: That in these cases, however, the condition is so rare as to make it difficult to suppose that, under ordinary conditions, the blood state could be the direct result of them.

Third: That, in all cases in which there has been any other tangible cause, it has hardly been sufficient of itself to produce the disorder.

(There is too much gastritis, too much Bright's disease, too much misery seen without any such effect, and the same is true of every other cause.)

Fourth: Let there be congenital or acquired weakness of blood-forming organs, and then, as various authors suggest, it is conceivable that by a "vicious circle" the condition may result.[1]

Fifth: That, after all known possible causes have been excluded, there remain certain cases for which no plausible explanation can be offered.

Finally, I would direct attention to the fact that in many cases, whatever be the supposed cause, there is a history of long-continued gastro-intestinal disturbance before the onset of the pernicious symptoms. In view of this, is it not possible that some of the cases are the result of poisoning by substances produced in the gastro-intestinal tract? If there be such a possibility, should not our efforts be directed toward cleaning out this tract in all primary cases?

I do not wish to say that my definitions are the best. I do not mean to imply that my conclusions are altogether justified by facts, nor do I say that they are original. I simply ask you to accept the former and discuss the latter. The time is short for discussion. What I want to ask I hope I have made clear. I beg that, if anyone think this paper worthy of discussion, he will not quarrel with these definitions, but will regard the questions suggested and any others bearing upon the disorder, as I have defined it. I give the definitions merely that all may understand what is meant. They are simply intended for present use, and I think they will serve their purpose.

To Relieve Chilblains.—Dissolve an ounce of ammonium chloride in half a pint of cider vinegar, and apply frequently. A half-pint of alcohol may be added to this lotion with good effect.

[2] Pepper.

[3] Zeitschft. f klin. Med, vol xiii., No. 5, 1887.

[4] The St. Gothard cases, it must be noted, in which the symptoms were relieved by the expulsion of an intestinal parasite, were under bad hygienic surroundings, as well as suffering from the worms. Both the surroundings and the worms may have had their influence.

[1] It is a fact well known that the human body, unlike the "one-hoss shay," usually "breaks down and doesn't wear out." It is quite possible that the blood formation, being weak in some people, "breaks down" first.

WORMIAN BONES IN FONTANELLES AND THEIR EFFECT IN CHILDBIRTH.[1]

By GRACE PECKHAM, M.D.,

NEW YORK.

THE occurrence of Wormian bones in the anterior and posterior fontanelles, as well as along the lines of sutures, is not perhaps infrequent, but the relation which these bear to the moulding of the skull in childbirth, so far as I can ascertain, has never been discussed. My attention was called to the possibility that such bones, if of considerable size and occurring in the posterior fontanelle, might exert a detrimental if not fatal influence upon the child, by three cases which occurred while I was interne at the New York Hospital for Women and Children.

The histories of these three cases were almost identical. The mothers were all primiparæ, and there was nothing abnormal either in the measurements of the pelves of the mothers or of the heads of the infants. The presentations were all of them the usual left anterior occipito-iliac. The labors progressed slowly but normally through the first stage, but the second stage was very slow, lasting between two or three hours in each case. Instruments were not used in either instance, as there was a constant expectation that the labors would terminate naturally.

The irregularity of the fontanelle could be very easily detected. In the first two cases it gave rise to confusion in determining the position, but in the third and last case, having had the experience with the two others, there was no difficulty in discovering that the posterior fontanelle contained Wormian bones. Each child was stillborn. The skulls of two were preserved, one of which is now shown. The other was almost exactly like that shown in Fig. 1. The family would not permit an autopsy to be made upon the third child, but took it away for burial. It could, however, be easily felt that the condition was similar to that seen in this skull, and that the shape and number of the bones were the same.

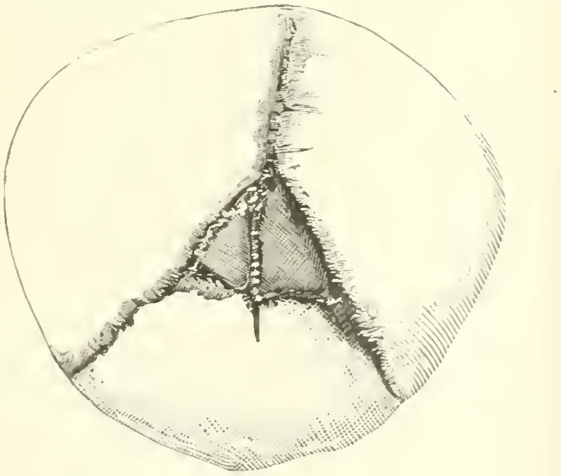

FIG. 1.

In regard to the formation of Wormian bones, Meckel states that often isolated osseous germs develop at the circumference of the occipital bone and unite themselves with it. Sometimes, though rarely, thicker ones develop about the articular regions; when there is an arrest of evolution of one or more of these inferior centres, Wormian bones are formed.[2] According to Broca[3] and Gosse[4] Wormian bones are an arrest of ossification; the latter attributes it to a rachitic or scrofulous condition, or the effects of violent pressure or hereditary transmission, and Topenjard[1] also speaks of them as an arrest of development.

Considerable ethnological interest has centred upon the occipital bone, and a number of learned and interesting papers have been written by distinguished anthropologists upon the subject. M. Bellamy in 1842 presented the mummy of a small child which had the interparietal bone. M. Rivero and M. Tschudy in the "Antiquités Péruviennes," published in 1851, gave drawings showing the bone which Anoutchune, after making studies of skulls in various museums, announced was to be found in twenty per cent. of the Peruvian skulls. The name "the bone of the Incas" was given to it. The question among the *savants* arose as to whether this was a mere anomaly or a reversal to a lower type, since the interparietal bone occurs in rodents, ruminants, dogs, and cats.

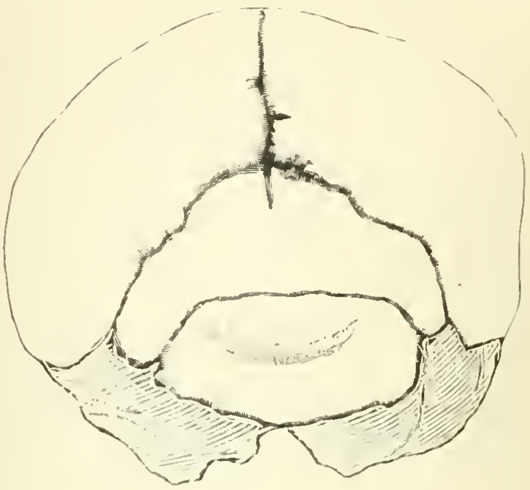

FIG. 2.—Interparietal bone, or bone of the Incas.

It is not out of place to refer to this matter of the interparietal bone in the matter under discussion, since it may be confounded with Wormian bones in the posterior fontanelle. The upper portion of the occipital bone is supposed to develop from four osseous centres which are separate in early fœtal life but gradually coalesce. The lateral union is accomplished first, and afterward the two segments above and below unite. When this latter fails to take place the interparietal bone is formed. The recent line of union shows very well in the skull of the new-born infant. Cuvier, Milne Edwards,[2] Geoffrey St. Hilaire,[3] and the other writers already mentioned insist that a distinction should be made between the interparietal bone and the large fragments occurring in the posterior fontanelles, which are true Wormian bones; the *os Èpactal* of some, the *os lambdoid* of others, so called because occurring more frequently in the posterior than the anterior fontanelle. These bones may be single or multiple, two, three, or four, and even as many as eight, according to one writer, quoted by Geoffrey St. Hilaire.

These cases are presented to the profession to call attention to the fact that large Wormian bones occurring in fontanelles may prove at the birth detrimental to the child. Especially if present in the posterior fontanelle they would prevent the overlapping at the sutures, and at the time the pressure would be greatest during labor, that is, during the second stage, cause an injury to the contents of cranium, and inflict such damage to the nerve-centres, probably those at the base of the brain, as to prove fatal. The practical question then arises, could this be avoided by the prompt and early use of instruments?

It is hoped that obstetricians will record cases of a like nature and report upon them with a view to determining the effect of these Wormian bones occurring in the fontanelles at childbirth, a point upon which obstetric literature up to this time has preserved silence.

IDIOPATHIC MULTIPLE CRANIAL NEURITIS.

By L. B. GRADDY, M.D.,

OMAHA, NEB.

On June 4, 1886, I was consulted by Miss L——, a strong, healthy woman, twenty-four years of age, who stated that for several days she had been seeing double. The only illness that she had ever suffered from was an attack of typhoid fever a year before, from which she perfectly recovered. She has never suffered from headache nor neuralgic pains about the head or face. There is no history of injury, recent exposure to draught of air, or change of temperature. Syphilis is easily excluded. Skin, kidneys, and other organs perform their function properly. Menstruates normally.

Examination showed marked paresis of the inferior and internal recti muscles of the right eye, motility being restricted downward and inward only. Other muscles normal. Tn. Fundus normal, $V. = \frac{20}{20}-$. Left eye normal. I prescribed for the symptoms, treatment consisting of laxatives, tinct. ferri perchlor., tinct. nucis vom., and the faradic current daily.

There was no material change in them for several days, when the whole cone of ocular muscles began to participate in the paresis, and on the 14th ptosis was added to the symptoms. On the 15th and 16th motility was still further restricted, reaching greatest restriction on the 17th, when the eye, hidden by the upper lid, was practically stationary, there remaining only the slightest movement upward. From the 17th improvement began, and went steadily on to complete restoration of motility at the end of a month from the beginning of the attack, at which time the diplopia had disappeared. The contractor pupillæ and ciliary muscles were at no time affected.

On July 23d Miss L—— returned, complaining that vision in the right eye was reduced. At this time she was seen by my associate, Dr. H. Gifford. Motility of eye normal, pupil somewhat sluggish; accommodation unaffected. Outlines of disk slightly blurred and slight opacity of the retina, especially above and below. Tn. $V. = \frac{20}{100}$. Color-sense impaired. Left eye normal. Mercurial inunction, pot. iod., and Glauber's salts were ordered.

July 24th, neuritis more pronounced; temporal side of papilla slightly swollen; $V. = \frac{20}{200}$.

July 25th, fundus appears the same; $V. = \frac{3}{200}$.

July 28th, no change in fundus; $V. = \frac{5}{200}$.

From this date vision improved steadily and the neuritis gradually disappeared. The date is not noted, but when vision had reached nearly normal the inunction and pot. iod. were discontinued and strychnia administered hypodermatically.

September 10th, a little haziness left at inner side of the nerve; $V. = \frac{20}{20}-$.

November 5th.—Patient returned with well-developed paresis of the muscles of the left side of the face. Nasolabial fold obliterated; logophthalmus; eyes normal. The patient at this time was placed in charge of her brother, a general practitioner in the city, and received potassæ iodidum only. In the course of a few months the paresis nearly disappeared.

October, 1887, eleven months from last date, Miss L—— reported having had no further trouble of any kind. Eyes normal; reflexes good.

By request, Miss L—— reported again on February 15, 1888. She was perfectly well, and, aside from a slight stiffness of the muscles of the left side of the face, no trace of her former trouble remained.

To sum up briefly: We have here a healthy young person, attacked by successive paresis of the third, fourth, and sixth nerves of one side; after an interval of six weeks an optic neuritis of the same side; another interval (three months) and a paresis of both branches of the seventh nerve on the opposite side is developed.

Aside from the multiple neuritis of syphilis and alcoholism, cases like the foregoing are extremely rare. In the ophthalmological literature I find but two cases mentioned, neither of which can positively be classed with this one: The first by Schweigger (Zehruder's *Monatsblätter f. Augenheilk.*, xii., 21), in which an abducens paralysis of the left side was followed within a few weeks by a sudden and marked diminution of vision with normal fundus. This condition remained unchanged as long as the patient was under observation. The second is by Hutchinson ("Graefe-Saemisch," v., 816), in which sudden failure of sight occurred in one eye, with paralysis of the third nerve. Slight improvement occurred in the paralysis and the vision as well. Failure of sight in both these cases was attributed to retro-bulbar neuritis.

Unverricht (*Fortschritte de. Med.*, December 15, 1887) reports a case where all the cranial nerves were affected one after the other by minute sarcomatous metastases between the dura and the calvaria. He also mentions four other cases of multiple cranial neuritis, all of which were of syphilitic origin.

In considering the etiology of the paresis in the case here reported, we have to choose between emboli, multiple hemorrhage, and neuritis. Emboli and multiple hemorrhage can be practically excluded by the good health of the patient previous to the first and subsequent to the last attack; the gradual progression of the affection of the ocular muscles; and, finally, by the positive information furnished by the optic nerve lesion.

The peripheral nature of the lesions is indicated by the optic neuritis, and by the fact that both branches of the facial were involved; it having been long ago asserted by Trousseau that central lesions generally affect but one of the branches of the facial. This theory of Trousseau is strongly supported by the experiments of Mendel (*Berlin. klin. Wochenschrift*, 1887, 48), which indicate that the orbicular branch of the seventh has a separate origin, its nucleus being close to that of the oculo-motorius.

In referring to the treatment, it is scarcely necessary to say that the treatment adopted in the first attack points to the fact that the pathological condition was not recognized at the time, a very common error doubtless in ocular and facial paralyses. Recovery was nevertheless perfect. The optic neuritis furnished a clew to the pathological condition, but the full import of the clew was not appreciated, which explains why the patient received potassæ iodidum only for her facial paresis.

This case furnishes a valuable lesson in the parallel between restricted motility and reduced vision. This would indicate, taking a given case of idiopathic paresis of any of the ocular or facial muscles, that neuritis is present, and would warrant the adoption of that course of treatment known to possess the highest therapeutic value in neuritis, upon the supposition that neuritis is present.

GALL-STONES OR SOAP?—Dr. Thos. W. Street, Surgeon U. S. N., writes: "In reading the communication under the above title in THE MEDICAL RECORD, I was reminded of a case in point in my own practice which may help to answer the query. I gave two large doses of olive-oil in a case of hepatic colic, and left instructions to have the stool carefully preserved, washed, and strained. The next morning the apothecary informed me that the man had been passing dried apples. The residue from the stool, saved for my inspection, certainly did resemble, in form, color, and feel, macerated dried apples; but after it had been put in the sun and thoroughly dried, its true nature was revealed. The particles had shrunk to one-fourth or more of their former size; they were hard, and exhibited *facets*, thus proving them conclusively to be gall-stones."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, April 14, 1888.

THE APPEAL OF THE NEW YORK ACADEMY OF MEDICINE.

WE take great pleasure in calling the attention of our readers to the appeal of the New York Academy of Medicine for contributions to its building fund. The circular letter issued contains so many facts of interest about the Academy and its work that we incorporate a considerable part of it here.

The Academy is forty years old; it now has a membership of over 500. It supports a library which contains 37,000 volumes and 20,000 pamphlets, and a *free* reading-room, in which are nearly all the medical journals of the world. Both library and reading-room are free to the medical profession and the public.

The Academy has already accumulated some property. It owns its present building, free of debt, and through legacies and donations it has acquired $100,000.

Its present quarters are sadly inadequate to the needs of the Society, and the library is in constant danger of destruction by fire. A new fire-proof building is therefore urgently needed, and the sum of $250,000 is asked for, in order to buy the site and erect a building suitable to the work of the Society.

An appeal for this money is made to the public, as well as to the profession, on the following grounds:

"The Academy is not connected with any school or college. It is self-supporting, and carried on in the interest of the whole profession. There are no fees nor emoluments of a private or individual nature. It is not supported nor subsidized by the State or municipality. Its aim is the elevation of the profession to a higher scientific standard.

"On the knowledge, wisdom, and public spirit of the medical profession, the hygienic and sanitary safety of the country is dependent. If our great city and the republic will be better protected in future than heretofore against the inroads of cholera and other infectious diseases, that result will be due in great part to the efforts of the New York Academy of Medicine."

The appeal continues:

"Will not generous and patriotic New Yorkers feel a just pride in seeing our city possess another monument devoted to science; established on a firm and liberal foundation; a protection, an honor, and a credit to its citizens, emulating, if not surpassing, the great institutions of a like character in the old capitals of Europe?

"In this conviction we confidently hope that a fund will soon be raised sufficient to purchase a proper site and to erect upon it a building specially adapted to our Society, and which, for generations to come, will be sufficient for its purposes. This building once paid for, there will be no further occasion for us or our successors to call upon the liberality of our fellow-citizens.

"Contributions and correspondence may be addressed to members of the committee at their residences, or to the care of the New York Academy of Medicine, 12 West Thirty-first Street, New York. Committee: Dr. Abraham Jacobi, Chairman; Dr. Joseph E. Janvrin, Treasurer."

The committee embraces a large number of representative members of the profession, and it is indorsed by many public-spirited laymen.

We wish every success to the work.

CEREBRAL LOCALIZATION AND BROWN-SÉQUARD.

DR. BROWN-SÉQUARD has an ingenious and original mind, and an indefatigable industry in the study of scientific problems and the pursuit of his, often fantastic, theories. He has always with great consistency opposed the views of cerebral localizationists, or "cluster-localizers," as he calls them, and in *The Forum* for April he presents his matured opinions upon this subject. His article would attract no attention and deserve no notice if it appeared in a scientific periodical. For it contains nothing but assertions which are misleading, and arguments based on imperfectly made observations, or carried out with incoherent logic. The fact is that the doctrine of localization is one now so firmly established and so widely accepted that it is folly to argue with those who oppose it. Cerebral localization is a demonstrated fact, and nothing new is presented by Brown-Séquard in his latest attempt to controvert it.

CONCERNING APOTHECARIES WEIGHT.

IT is a pity that the world has not yet found a *Volapük* of weights, as Volapük is a language which can be universally and very quickly learned, because stripped of the perplexing irregularities of declensions and conjugations which make the pathway thorny to the striving student who is attempting to acquire a tongue other than that of his mother. So weights and measures should be reduced to a universal basis.

We are aware that this is no new plan we are advocating, that those who believe in the metric system have been strenuous in their efforts to have this prevail; but Dr. Oscar Oldberg[1] gives such cogent reasons for the setting aside of this system, which he previously upheld, that we cannot refrain from quoting them and saying, "How now?"

"Whilst still impressed with the admirable characteristics of the metric system which distinguish it from all others, the writer has been reluctantly obliged to surrender his former view, for reasons hitherto not patent to him, by which he has become convinced that the weights and measures of that system are not the best for use in practical medicine and pharmacy. One reason why a decimal system is inadequate for the peculiar requirements of medicine and pharmacy, is to be found in the fact that an easy, natural subdivision of doses, and a clear understanding of the active contents and the use of liquid remedies, require the employment of such units of weights and of volume as are not only parallel and commensurable, but at the same time capable of progressive subdivision by two, into lower units, without fractions. The introduction of parts by weight to the exclusion of fluid measures in the formulæ for liquid preparations in our Pharmacopœia is, therefore, in the writer's belief, to be regretted. Another grave objection to the use of the decimal system in medicine and pharmacy, is to be found in the fact, brought to our attention by fatal results, that the safety of human life ought not to be allowed to depend in any degree upon a decimal point, which may be misplaced, misunderstood, omitted, or illegible."

---

[1] A Manual of Weights, Measures, and Specific Gravity, by Oscar Oldberg, Phar. D., Chicago.

IODOL AS A SUBSTITUTE FOR THE IODIDES AND IODOFORM.

Much has been said of late regarding the value of iodol. On the whole, it has not made as yet a great impression. But it is destined to do so, according to Dr. George Assaky, who, in the *Archives Roumaines* for November, 1887, contributes a second article, recording his experiences with the drug.

Iodol, or tetraiodopyrrol (C_4I_4NH), is a brownish-yellow powder, inodorous, almost insoluble in water, but soluble in alcohol, ether, and fats. It contains about eighty-eight per cent. of iodine, and is less rich in that element than iodoform. Taken into the system it is excreted as iodine in the urine. It is about one-third less poisonous than iodoform, but its toxic phenomena are the same. It can be given internally in doses ranging from gr. v. to gr. xv. "It is better borne than iodoform, and sometimes acts much better than iodide of potassium" (Pick).

The first therapeutic researches were made by Wolff, in 1885. In these it was simply shown that iodol was a good antiseptic. In the same year Mazzoni reported upon its use topically in venereal diseases. He particularly claimed that no erysipelas followed its use, as sometimes happened with iodoform. In 1886 Benno Schmidt, A. Trousseau, L. Suquet, G. Ferrand, F. J. Pick, and Mazzoni published communications. Marcus tested its toxic properties, while Pick used it internally. He never observed poisonous symptoms or iodism, and, like other observers, he found that iodol was much more slowly eliminated than the iodides.

Assaky, in his two communications last year, dwells especially upon the value of iodol in surgery, where he thinks it superior to iodoform; but he also places a high estimate upon the drug as an internal agent. It has, he says, "marvellous effects" in tertiary syphilis and scrofula, acting more quickly than the iodides.

THE EFFICACY OF LARGE DOSES OF ARSENIC IN CHOREA.

The curative property of arsenic in certain forms of chorea is well attested by numerous unimpeachable observations. It is equally certain, however, that arsenic does not always cure. Dr. James Sawyer, in an article published in *The Birmingham Medical Review*, maintains that when arsenic fails to manifest its ordinary therapeutic efficacy, it is because the drug is not administered in the right way. Properly exhibited, he regards its action as little less than specific. According to him, in order to get the best effects of arsenic in chorea, the remedy must be employed in large and increasing doses. The medicine may be safely "pushed" until irritative vomiting is excited. As with other drugs, some manifestation of physiological action coincides with the direct therapeutic effect of the remedy. It may be remarked in this connection, however, that irritative vomiting belongs rather to the pathological than the physiological effects of arsenic, a fact which Dr. Sawyer's enthusiasm for this remedy may have caused him to overlook.

The author describes a typical illustrative case as follows: "A little girl, aged ten years, weakly and neurotic, has subacute, general chorea. I give her five minims of Fowler's solution of arsenious acid, in an ounce of water, thrice daily. In three days, the dose is increased to ten minims; in three days more, to fifteen; in three days more, to twenty; and so on, until she is taking thirty-five minims of the solution, or a little more than a fourth of a grain of arsenious acid, thrice daily. From the commencement of the treatment, the choreic movements gradually subside in severity, in frequency, and in extent of distribution, and when the large dose of more than half a drachm of Fowler's solution is attained, the movements entirely cease, and a little vomiting and stomach-ache warn us that we have reached the earlier physiological manifestations of our remedy. We then withdraw the drug altogether for two days. Afterward, for a few days, we give a reduced dose, ten or fifteen minims of the solution; then the remedy is finally discontinued. The child remains well. After a fortnight's further observation, she is dismissed from our care, cured."

Perhaps the author claims too much for his favorite remedy. But it may be well, in suitable cases, where moderate doses of arsenic have failed, to test the therapeutic efficacy of the drug in the larger doses employed by Sawyer.

SUPPURATION AND SEPTIC DISEASES.

Dr. Watson Cheyne has recently completed a series of lectures in which he gives additional evidence, if any were needed, of the intimate relation between micro-organisms, suppuration, and septic diseases. But he also shows that, while this relation is certain, the beginning and end of wound-treatment is not by any means simply the problem of keeping out these germs. In the production of septic troubles, he says: "Much depends on other conditions, of which the chief probably are the dose or number of the organisms and their concentration, general and local depression of vitality, and the seat of inoculation. If the organisms enter in large numbers, sufficient to overcome the resistance of the body, they alone may cause the disease; frequently, however, they enter in smaller numbers, and then other conditions become necessary to enable them to act. Of these conditions the chief are depressed vitality, either local or general, combined with the possibility of their remaining in the weakened tissue. This depression of vitality may be brought about by conditions acting on the body generally, such as acute fevers; or by local conditions, more especially those which induce the early stage of inflammation, such as cold, injury, chemical substances, the products of the bacteria themselves, or the products of other kinds of bacteria which may happen to be growing along with them. Or, again, the favorable condition may be some peculiarity in the soil, as shown by variations in the character of the disease in accordance with the seat of inoculation and the anatomical arrangement of the part. The only factor, however, with which we can reckon with certainty is the cocci themselves." Outside of the body the pyogenic micro-organisms are not easily found under ordinary conditions. Very few exist in the air, but sometimes they have been detected in surgical wards. One of the most common seats of them is the human skin, especially the folds and moist parts. They occur also in the mouth and pharynx. Dr. Cheyne thinks that they most frequently get into wounds by developing between the skin and the dressings, and in consequence especial care should be taken thoroughly to disinfect these parts.

THE TREATMENT OF PAUPER AND INDIGENT CONSUMPTIVES.

No hospital or the dispensary physician in our large cities can fail to recognize the utter feebleness and inutility of the present methods of treating pauper or indigent consumptives. Dr. Seibert has averred that among poor Germans dispensary treatment not only fails to cure but even sensibly to relieve this class. Dr. Paul H. Kretzschmar confesses to an experience nearly similar.

In the hospitals the story is not quite so bad. Many patients in the first stage improve for a time, but the percentage of cures is extremely small, and most cases progress rapidly to the worse. In New York City there are some thirty thousand cases of consumption, with five thousand annual deaths. If society provided sufficient means of treatment, at least fifteen or twenty per cent. of them could be cured and restored to useful citizenship. While we are spending so much money to keep out cholera, or stop the ravages of acute infectious fevers which kill fewer than does phthisis, would it not be wise to spend some energy upon this last disease? Such is the plea made by Dr. Paul H. Kretzschmar in an article in the *New York Medical Journal* entitled "Dr. Dettweiler's Method of Treating Pulmonary Consumption."

The description given of Dr. Dettweiler's Sanitarium at Falkenstein shows how much can be done by systemized efforts to treat this disease. The statistics, which are most carefully and conscientiously prepared, show that in the first stage fifteen to nineteen per cent. can be cured; that, taking all cases, about thirteen per cent. can be cured, and eleven per cent. be "relatively cured." Dr. Dettweiler even claims that, under appropriate treatment, if the disease has not made too much progress, over one-half the cases of bacillary phthisis can be cured. Dr. Dettweiler's method of treatment involves no expensive apparatus, costly drugs, or elaborate appliances of any kind. It consists essentially in the use of fresh air, liberal food, and alcohol.

The cost to the patient at Falkenstein is about three dollars per day, and it is evident that such a sanitarium as Dr. Dettweiler conducts could not be supported as a public charity. But the essentials of his treatment might be applied. Instead of sending phthisical cases to the crowded wards of city hospitals, there might be country branches established for such cases; or the phthisical service of the city hospitals might be specialized in suitable pavilions.

The treatment of pauper and indigent consumptives is a measure that heartily deserves the consideration of the benevolent in all our large cities, as well as those concerned in the purely economical side of social questions.

DANGEROUS INFLAMMATION OF THE EAR—SENATOR CONKLING'S CASE.

THE case of Senator Conkling, which is now engaging so much of public attention, illustrates in a striking manner the grave results of extension of the inflammatory process from the middle ear to the brain. It is quite probable that the initiative attack was otitis media, which was attended with suppuration in the tympanic cavity and the adjoining cavity of the antrum. Nature failing to make an exit for the pus through the drumhead, the disease extended itself to the mastoid cells and the meninges. The usual severe symptoms manifested themselves, when Dr. Fordyce Barker was called to prescribe for what the patient supposed was a simple "boil in the ear." The grave aspect of the disease is explained by the broken-down condition of the patient at the time of the attack, it being well known that under such conditions the inflammatory process is virulent, and apt to extend into neighboring parts, involving not only the mastoid cells but the meninges of the brain and the periosteum overlying the mastoid.

The management of these cases is manifestly in the direction of prompt evacuation of pent-up secretions. At the earliest possible moment a free incision is to be made in the abscess, which in these cases is far up into the tympanum, and which is not generally reached by the ordinary puncture of the drumhead. When the disease has progressed further, Wilde's incision and perforation of the mastoid give relief, but, unfortunately, both operations are resorted to when too late to be of any benefit. It is to be hoped that in the case of the distinguished senator the rule regarding the operation may have its exception, and ultimate recovery take place; but, as purulent pachymeningitis has already declared itself, the chances are on the wrong side.

DEATHS FROM PYROGALLIC ACID.—The editor of the *Druggists' Circular* says that a druggist received a prescription from an eminent physician for a mixture containing pyrogallic acid in five-grain doses. The pharmacist hesitated about filling the prescription; he consulted the doctor, was told it was all right, and then prepared the medicine. The patient, a young man, died within twenty-four hours. The pharmacist was afterward asked to compound the same mixture for another patient, a young lady, for whom the same doctor had prescribed it. This time he positively declined to prepare it; the prescription was obtained from another pharmacy, and after taking three doses the patient died. This story, if true, is a most extraordinary one, and almost deserves a police investigation. Pyrogallic acid is derived from gallic acid by heating and driving off the CO_2. Its dose is not usually given in text-books.

News of the Week.

State Society Meetings in April.—The Alabama State Medical Society, at Montgomery, April 11th. Dr. E. H. Sholl, President; Dr. T. A. Means, Secretary.

The South Carolina State Medical Society, at Columbia, April 14th. Dr. T. Simons, President; Dr. J. L. Dawson, Secretary.

The California Medical Society, at San Francisco, April 15th. Dr. R. H. Plummer, President; Dr. W. A. Briggs, Secretary.

The Georgia Medical Society, at Rome, April 18th. Dr. A. G. Whitehead, President; Dr. A. B. Ashworth, Secretary.

The Mississippi State Medical Society, at Jackson, April 18th. Dr. N. L. Guia, President; Dr. W. E. Todd, Secretary.

The Texas State Medical Society, at Austin, April 18th. Dr. S. R. Burroughs, President; Dr. F. E. Daniel, Secretary.

The Louisiana State Medical Society, at Munroe, April 21st. Dr. J. Jones, President; Dr. P. B. McCutcheon, Secretary.

The Arkansas State Medical Society, at Fort Smith, April 25th. Dr. W. P. Hart, President; Dr. L. P. Gibson, Secretary.

Government and the Arkansas Hot Springs.—Dr. Keller, of Hot Springs, wishes the Government to exert actual, in place of nominal, control of the Springs, and drive out quacks.—*Medical Standard.*

A Hospital to Cost $100,000 is to be erected at Grand Rapids, Mich.

Compulsory Notification of Infectious Diseases by Physicians.—A bill has been introduced into the Legislature making it penal for physicians not to report births and deaths. It ought not to pass.

The Pros and Cons of Hypnotism.—Professor Voisin claims to have cured an inveterate liar of his evil habit by mesmerism. Professor Voisin is not wanted by dealers in patent medicines. A physician in Carlsruhe hypnotized a young man, who remained in the trance state for eighteen hours and then became maniacal.

The Governor of Minnesota some time ago appointed the following commission on Insane Hospitals: Drs. Perry H. Millard, of St. Paul; Henry W. Brazie, of Minneapolis; and A. H. Collins, of St. Peter. The former commission is abolished, and the following resignations were necessary: Drs. C. H. Boardman and G. W. Wood, of St. Paul, and W. H. Leonard, of Minneapolis. The conditions which hampered the old commission are removed, and increased powers given. Dr. Millard was made president, and Dr. Collins secretary. The commission recommends the employment of more medical assistants, including one lady, and a special pathologist in each State insane hospital.—*Medical Standard.*

Cholera *vs.* Medical College Commencements.—In his address as President of the Chicago Medico-Legal Society, Dr. E. J. Doering said: "I question which is the greater public calamity, an occasional epidemic of cholera, or the regular, recurring annual epidemic of some 4,000 doctors let loose on an innocent and unsuspecting public. . . . The action of our diploma-mills, in adding each year thousands of young men to the ranks of a profession already filled and overflowing, is rapidly producing an army of genteel paupers, too proud to beg, too honest to steal, but too poor to exist. . . . No reform can be expected from the colleges, for obvious reasons; for, managed as they are, as private enterprises for business purposes solely, they naturally resist anything calculated to impair the very object for which they exist. As in a free country like ours it is unfortunately impossible to cause the 'professors' to be imprisoned at hard labor and the colleges to be burned down, we have to seek elsewhere for relief."

Copies of the Medical and Surgical History of the War are getting scarce and expensive. A bill has been presented by Hon. W. J. Stone, of Kentucky, providing for printing additional copies.

A Medical "Trust."—A physician of Spencerville, O., writes to the *Medical Standard:* "The physicians of Spencerville and vicinity have combined for protection against delinquent debtors. The plan adopted is as follows: The physicians make out and exchange lists of patients who are delinquent debtors. All agree to refuse medical aid to such delinquents except for cash. The plan has worked like a charm, and many old debts are being paid. Let physicians elsewhere do likewise."

Druggists and the Prescription of Poisons.—The Indiana Legislature has passed a law declaring that "From and after the passage of this act, no pharmacist, druggist, apothecary, or other person, shall refill more than once prescriptions containing opium or morphine, or preparations of either in which the dose of opium shall exceed one-fourth grain or morphine one-twentieth grain, except with the verbal or written order of a physician." A violation of the law is declared a misdemeanor, punishable by a fine of not less than ten or more than twenty-five dollars.

Furrows on the Finger-nails.—Nearly twenty years ago Dr. Wilks directed attention to the fact that a transverse furrow appeared on the nails of the hand after a serious illness. Medical literature has since then contained a few references to the subject; he again brought the subject before the Pathological Society at its meeting on March 20th, and related a remarkable case. In that case the furrow was caused by three days' sea-sickness.

Erythrophlœin.—At a recent meeting of the Academy of Medicine, M. Panas communicated the results of experiments with erythrophlœin, which he had tried on human eyes, and on those of the lower animals. He states that this substance has a positive anæsthetic effect, which lasts longer than that of cocaine. He considers it objectionable, however, on account of the violent pain and inflammation which it causes. M. Panas prefers cocaine, and condemns erythrophlœin in ophthalmic surgery; he had used it in treating granulations and granular pannus, but the results were not satisfactory.—*British Medical Journal.*

Alcohol and Heart Disease.—Dr. George Harley ends his lectures on the effects of moderate drinking upon the human constitution with the following conclusions: 1.

That alcohol, when indulged in, even well within the limits of intemperance, has a most prejudicial effect on heart disease. 2. That sudden spurts of muscular exertion act most deleteriously on all forms of organic cardiac affections. 3. That mental excitement is a cause of rupture of atheromatous blood-vessels. 4. That a mere extra-distention of a stomach by wind may suffice to fatally arrest a diseased heart's action. The knowledge of these facts has for some years past led me to make it an invariable rule to impress upon all patients laboring under diseases of the circulatory system, who desire to minimize the effects of their complaints and ward off as long as is possible the inevitably fatal termination, to pay strict attention to what I call the following three golden rules: (1) Take exercise, without fatigue; (2) nutrition, without stimulation; and (3) amusement, without excitement.

In Conferring a Decoration upon Sir Morell Mackenzie, the Emperor Frederick said: "When you came the first time I confided in you, as you were recommended by my German physicians. I have since had occasion in my own experience to value your capability. I am glad to bestow upon you this order in thankful acknowledgment of your merits and in memory of my accession to the throne."

The Appointment of Dr. John M. Browne to be Surgeon-General of the Navy, to succeed Dr. Gunnell, whose term of office expired March 26th, has met very general and hearty approval in medical circles. Dr. Browne has been in the service for thirty-five years, and brings to his new position an unusual degree of executive skill, as well as of medical and scientific attainments.

The Irish and our Public Charities.—Mayor Hewitt shows, in a recent letter to the Board of Aldermen, that while the Irish constitute less than a sixth of the population of New York, they constitute more than a fourth of the Board of Aldermen, more than a fourth of the police, and more than a third of the sick, paupers, and criminals supported by the city.

Seventh Meeting of the International Ophthalmological Congress.—At the meeting of the Heidelberg Ophthalmological Society held last year, it was decided to celebrate the twenty-fifth anniversary of the society by inviting the ophthalmologists of all countries to attend its meeting to begin August 9, 1888, and by their presence to expand the meeting of the local ophthalmological society into an International Congress. A committee was intrusted with the preparations necessary for the carrying out of this plan. The committee consists of Drs. Otto Becker, William Hess, and J. Stilling.

The Medical Colleges of New York have nearly all closed their season's work, and it has been a laborious one. The College of Physicians and Surgeons is credited with about eight hundred students. Bellevue and the University have had about seven hundred each. The Woman's Medical College, whose requirements are the most exacting despite its limited financial resources, has about fifty students.

Oil of Peppermint, in vapor diluted even to 1 part in 100,000, kills cockroaches in an hour, they dying in convulsions. This is a fact of interest to doctors' wives, if not to doctors. As for bacilli, Babes says that one drop, placed under a bell-jar covering a cultivation of cholera bacilli, will kill both bacilli and spores in forty-eight hours. Mr. W. Leonard Braddon praises the oil also as among the best of surgical antiseptics, and as of value in phthisis and diphtheria.

Dr. Maurice N. Miller sends the following note: "An editorial in your last issue upon the present status of laboratory instruction in our medical colleges is, in the main, most excellent and seasonable; but I beg to ask correction of a statement or two, which, if allowed to stand, would materially injure the institution with which I have the honor to be connected. You may reasonably lament the very general want of endowment for the purpose of establishing free medical laboratory courses, but, as a matter of justice, it should be known and recorded that the laboratories of biology and pathology connected with the University Medical College have provided regular courses of instruction of eight months' duration for the past six years, *and that this amount of instruction has been given without charge.* Every student graduating from this institution within the period named has been furnished with the use of a microscope and the materials necessary for the mounting of objects. The course includes both normal and pathological histology, and is directed toward a preparation for the appreciation of the morbid processes in disease rather than to the technique of microscopy. Ample provision has been made for advanced work at a nominal cost. Over five thousand specimens have been mounted by these classes during each college session. Since the establishment of the Loomis Laboratories the courses in normal and pathological histology have been extended, they remain obligatory, and are continued without charge for instruction. It is true that, notwithstanding the most liberal foundation of these laboratories, a small tuition-fee is charged for work in advanced lines, and it is questionable whether endowment for special research would be profitable either to the medical or general public."

The Middleton Goldsmith Lecture for 1888 will be given by Dr. J. M. DaCosta, of Philadelphia, on Wednesday evening, April 18th, at eight o'clock, at the Academy of Medicine, 12 West Thirty-first Street, New York. Subject: "The Relation of the Kidney and Heart Affections." The profession is invited.

The Post-graduate Medical School held its third annual banquet, at the Hotel Brunswick, Monday evening, April 10, 1888. The President of the Faculty, Professor D. B. St. John Roosa, presided. Among the guests were Commissioners Porter, Simmons, and Brennan. The following gentlemen responded to toasts: Drs. Jacobi, Bryant, Dana, Simmons, Rev. Dr. Bridgman, and Mr. E. S. Fox. The Secretary, Dr. Rice, stated that the number of matriculants during the past season had nearly doubled, and that thus far two hundred and sixty-five had matriculated.

Dr. Nicholas Senn has been appointed Professor of the Principles of Surgery and Surgical Pathology in the Rush Medical College, Chicago.

Illness of Dr. C. R. Agnew.—We are pained to learn that our distinguished townsman is suffering from an attack of perityphlitis. No grave symptoms have as yet appeared, and his many friends will hope for his speedy recovery.

Reviews and Notices of Books.

Paralyses—Cerebral, Bulbar, and Spinal. A Manual of Diagnosis for Students and Practitioners. By H. Charlton Bastian, M.A., M.D., F.R.S. With numerous Illustrations. Pp. 671. New York: D. Appleton & Co. 1886.

Dr. Bastian has won for himself a deserved reputation as a student of biology and neurology; and a work from his hand is sure to have merit both scientific and literary. The present volume does not disappoint one. It takes the most striking, important, and often obscure of all nervous symptoms, viz., paralysis, and deals with it in so thorough a way that the reader can hardly fail to feel that he is getting all that is known upon the particular points he is investigating. Naturally the descriptions must take in some other things than paralysis, and the book is therefore in reality a tolerably complete contribution to neurological diagnosis.

Any work on a neurological subject must necessarily contain some imperfections, since the progress in this department of medicine is so rapid and continuous. This is especially true of local diagnosis, and the author is certainly behind the times already in his treatment of local diagnosis of cortical regions. The evidence, for example, with regard to the seat of vision has accumulated, until now we can speak of it with much greater certainty than is done by Dr. Bastian.

In his table of pathological causes of brain-paralyses we see no reference to polio-encephalitis, a condition which does undoubtedly sometimes exist. We would venture to criticise, also, the discussion of the focal lesions in the pons and medulla. It is a practical one, but we should have been glad to have had a clearer and more comprehensive discussion of the anatomy of those parts, without thoroughly understanding which the finer diagnosis certainly cannot be made. We would suggest, finally, that a book on paralyses needs, nowadays, to include paralyses from neuritis, and to have a fuller exposition of the methods of electrical examination than is here given. It is ungracious, however, to find fault with a work which, on the whole, is of so much value and interest.

Fever Nursing, Designed for the Use of Professional and other Nurses. By J. C. Wilson, M.D. Philadelphia: J. B. Lippincott Co. 1888.

This is one of the series of "Practical Lessons in Nursing," and consists of the lectures delivered by Dr. Wilson to the Nurse Class at the Philadelphia Hospital. The style is clear, concise, and comprehensive, and the work will prove valuable to physicians as well as to nurses, since it will assist them in issuing proper directions, as it brings to mind many practical details, and gives many useful suggestions which would help greatly in the careful management of a fever case.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S. The new American, from the eleventh English edition, thoroughly revised and re-edited, with Additions, by William W. Keen, M.D., Professor of Surgery, Woman's Medical College, Pennsylvania. To which is added Landmarks, Medical and Surgical, by Luther Holden, F.R.S. 8vo, pp. 1064. Philadelphia: Lea Brothers & Co. 1887.

This well-known "Anatomy," in its eleventh American edition, comes to us with the title-page well filled with references to work done by the editors, who have supplemented the labors of the author. It has been the standard upon which many have built, and its ability to support the superstructure proves its intrinsic worth. Dr. Keen has done his part in editing with great judgment and ability. The additions in cuts and text are of great value, and will add to the practical usefulness of the work, and to the needs of students in every department of medicine and surgery. It is rare that an editor can run the risk of substituting any part of a classical work with a success that would challenge criticism, but in the section on Brain this has been done with marked advantage. The amplification of other topics, such as those bearing on cerebral circulation, cerebral localization, the sympathetic nerve, sectional studies of the different regions of the body, has been accomplished with a like gratifying result. One hundred and thirteen new engravings have been added, of which many are original. Many of the old as well as of the new cuts are colored, to show the anatomical relations of blood-vessels and nerves. Holden's "Landmarks" form the usual appendix. Dr. Keen has also to this part added much that is new and valuable.

A Practical Treatise on the Medical and Surgical Uses of Electricity. By Geo. M. Beard, A.M., M.D., and A. D. Rockwell, A.M., M.D. Sixth edition. Revised by A. D. Rockwell, M.D. New York: William Wood & Co. 1888.

The fact that this book has seen a sixth edition affords ample proof of its excellence were such evidence required. One of the joint authors, Dr. Beard, has already been dead several years, but his excellent work, particularly in the domain of functional nervous affections, remains with us as a perpetual reminder of his literary fecundity and scientific perspicuity. In the present work Dr. Beard's handiwork is largely visible. Since his death, however, advances have been made, notably in the application of the electric current to the treatment of the affections peculiar to women. Dr. Rockwell has been quick to seize upon these new advances, and all the essential points connected with the subject as embodied in the recent publications of Apostoli and others will be found in this edition. Besides these adaptations of the current to the uses of the gynecological clinic, Dr. Rockwell has added much practical advice concerning the uses of electricity in cases of extra-uterine pregnancy. As we have already had occasion to observe in a former review of this excellent book, there is much suggestive matter contained among its pages—matter which is far above the conventional padding of mere text-books. Finally, the book is carefully written, is amply illustrated, and devoid of that exaggerated technicality which befogs rather than enlightens.

The Throat and its Diseases, including Associated Affections of the Nose and Ear. With one hundred and twenty illustrations in color and two hundred engravings, designed and executed by the author, Lennox Browne, F.R.C.S.E., Senior Surgeon to the Central London Throat and Ear Hospital. Second edition. 8vo, pp. 614. Philadelphia: Lea Brothers & Co. 1887.

The second edition of this work is a marked improvement upon the first, not only in the way of elaboration of many practical details, but in the more systematic arrangements of some of its important points. The changes have been in more than one sense fundamental.

The aim of the author has been to infuse an individuality in his work which, considering his large experience and accurate methods of observation, gives it a peculiar and lasting value to the laryngologist. With the true instincts of a teacher he endeavors, and with great success, to lay the broad foundation for a thorough knowledge of the technique of nose and throat examinations, not only by lucid descriptions, but by plentiful and striking illustrations. In the present edition we notice that the author has in a measure departed from his original design, by discussing pathological conditions associated with local appearances. This necessarily gives a wider scope to the topics under consideration, and leads to a more intelligent and satisfactory study of the etiology and the reasons for special treatment. There is, indeed, too much of a tendency in works of this kind to ignore general principles of pathology, and treat lesions as mere local and independent conditions. We accordingly congratulate the author on this departure, and would fain encourage him to do more in that line. While we must admit that laryngology has done much for the proper treatment of throat affections, and made possible the cure of many diseases heretofore considered incurable, it can by no means ignore their dependency upon general constitutional disturbances, which invariably precede and accompany the long line of catarrhal troubles. Our author wisely treats both conditions, the local and general, and thus places himself upon the broad, solid basis of common-sense therapeutics.

As a matter of course, in the technique of every specialty each author has his own methods, and to refer to them in detail would be to lengthen a book notice beyond necessary limits. Suffice it to say, however, that, unlike many laryngologists and rhinologists, he does not develop a hobby, but rather, by the painstaking study of his cases, endeavors to base his conclusions upon simple and bare facts interpreted by sound reasoning and practical experience. From such a stand-point, his teachings adapt themselves to the wants of the general practitioner in a way which one would hardly expect on cursorily glancing at the book.

A feature which will specially commend the work is the number of fine chromo-lithographic representations of typical throat lesions, drawn by the author, who proves himself as apt with the brush and graver as with the pen and laryngoscope.

A MANUAL OF ORGANIC MATERIA MEDICA. By JOHN M. MAISCH, Phar. D. Third Edition. Philadelphia: Lea Brothers & Co. 1887.

THE third edition of this work contains a description of the new drugs which have proved a right to recognition since the publication of the last edition. In glancing through it, the reviewer is impressed with the immense amount of substances of the animal and vegetable kingdom which claims the attention of the druggist. It is a pity that in this, as in other works of the same kind, and, in fact, in lectures on Materia Medica, a wider distinction cannot be made between the drugs which are of frequent use and those seldom or never thought of. For instance, orange-flowers are copiously illustrated and described, while licorice has but a short paragraph. As much attention or more is devoted to the description of marigolds, which are officinal, though seldom if ever thought of except as floral decorations, as to the useful peppermint. This is probably due to the fact that all the drugs must be dealt with after a procrustean method, and made to fall within the most succinct description possible.

The cuts are fine, and the book is well gotten up.

DISEASES OF MAN: DATA OF THEIR NOMENCLATURE, CLASSIFICATION, AND GENESIS. By JOHN W. S. GOULEY, M.D., Surgeon to Bellevue Hospital. Pp. 412. New York: J. H. Vail & Co.; London: H. K. Lewis.

THE author of this treatise has put forth a plea for greater precision in medical nomenclature, and has indeed given us a masterpiece of logic, well calculated to carry him successfully through his self-imposed labors in this very inviting field. He has given us a fine example of the developmental method in a spicy, lucid style, admirable for its conciseness and directness of statement. So exhaustively has he treated his subject that criticism regarding shortcomings or omissions is dumb. He has likewise vindicated his claim for conscientious endeavor by many references to philosophical, biographical, and historical authorities which show a wide range of reading, supplemented by much critical acumen. In fact, he has given us a ready-reference book on many topics of interest—a veritable epitome of the drift of opinion and the status of knowledge, which will prove of immense value to the medical historian, who, we are constrained to admit, is yet to appear. He has also displayed much philological ability in the definition of terms, and has sternly set his face against many an absurdity traceable to a departure from the anatomical method of naming in the synopses of Sauvage, Cullen, Parr, Good, and Delorme, presenting them in a manner calculated to convert to his own views.

To rescue the science of medicine from the chaotic condition of its nomenclature is no mean labor. At present it is a Babel of tongues, spoken by individuals with different inflections, and full of tributes to personal vanity and ever-increasing coinages, conveying meanings to no two investigators alike. Claims to priority or contemporaneous discovery are sometimes awkwardly blended in names of different nationalities, and, on the whole, very little basis is allowed for future additions. Against these fatal tendencies to inexactitude our author contends most manfully, and with a rare candor gives his authorities the benefit of their own full statements, and thus he escapes the injustice of divorced contexts as well as garbled extracts. He lays down, among many others, the axiom that diseases should be grouped, "in accordance with the apparatuses of the body, into families, branches of families, classes, orders, genera, species, sub-species, varieties, and sub-varieties." The source of confusion is due to the unsatisfactory fashion of appropriating any name which may strike the fancy or contain the germ of a simile. Why, we ask, may not medicine have its reforms as well as chemistry, or its stable methods as well as astronomy? The changes need not be violent, for many have unconsciously contributed to the reform, the fault having been that the labors have been spasmodic and merely adapted to the emergency. Presumably, however, we may not attain to the precision of mathematics, but there is at least some exhilaration in our approaches to it.

The success of our author, who, among his many literary virtues, writes attractively in the third person, is well pronounced. He has ventured upon a comparatively new field, and with a rare ability has communicated his own enthusiasm to the reader. He deserves as much credit as those reformers who, after many long struggles, have rescued the "Saxon pure and undefiled" from the grip of the "ponderous Johnsonese." We bespeak for the new classic frequent references, unavoidable quotations, the adoption of its many suggestions, and the honor of many editions.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. v. Edited by J. EWING MEARS. 8vo, pp. 386. Philadelphia: P. Blakiston & Son. 1887.

THIS is the best volume of the series, containing as it does surgical papers of rare merit. It contains twenty original articles, all of which deserve the careful study of every progressive surgeon.

A SHORT MANUAL OF SURGICAL OPERATIONS. By ARTHUR E. J. BARKER, F.R.C.S., Surgeon to University College Hospital, London. 12mo, pp. 415. London and New York: Longmans, Green & Co. 1887.

As its title indicates, this is a short manual of surgical operations. It has been the endeavor of the author, in a very limited space of four hundred pages, to condense and illustrate the practical operative surgery of the day. He has gone over the field very well, and has given his work a value which will be appreciated by younger surgeons who wish, in a compact form, a description of the more modern operations upon the brain, tongue, stomach, alimentary canal, and kidney. His descriptions are terse and intelligible, and prove him to be a practical surgeon, thoroughly alive to the details of his work.

TIGHT LACING LESSENS THE FLOW OF BILE, at least in rabbits. Such is the conclusion arrived at by Dr. W. J. Collins after a series of experiments. The unfettered action of the diaphragm is essential to the normal flow of bile.

Society Reports.

FRENCH SURGICAL CONGRESS.

Third Annual Session, held in Paris, March 12 to 17, 1888.

PROFESSOR VERNEUIL, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

MONDAY, MARCH 12TH—FIRST DAY.

THE opening session of the third French Surgical Congress was called to order by the President, on the afternoon of Monday, March 12, 1888. Delegates were present from Switzerland, Belgium, and Roumania, as well as from France.

M. **VERNEUIL** delivered the

PRESIDENT'S ADDRESS,

which was a defence of French surgery from the charges brought against it by critics of neighboring countries. In France, he maintained, there was just as much advance in the science and art of surgery as there was in other countries, only the progress was of a different sort. French surgeons were marching along none the less surely because slowly, and their route was along less dangerous paths. His colleagues did not make a daily practice of removing a larynx, or a pharynx, or an œsophagus, or a stomach; and it was not a very common thing for them to puncture the cavities of the heart. They were certainly less rash than the surgeons of Germany, England, or America, but perhaps their confiding patients were the gainers thereby. French surgery was eminently conservative, though it hardly deserved the appellation, which had been applied to it at the time of Lisfranc, of

POULTICE SURGERY.

But, for all their conservatism, French surgeons did not hesitate to use the knife freely, and to operate boldly when anything was to be gained by so doing. Their aim was, however, to do the most good to their patients, while exposing them to the least risk.

M. **OLLIER**, of Lyons, then presented a communication upon

RESECTION OF THE WRIST FOR ANCHYLOSIS.

He showed that there was formed over the ends of the bones an osteo-fibrous cushion, so that a new and very mobile articulation resulted. The movements of this new joint might imitate very perfectly those of the normal articulation. It was formerly thought to be absolutely necessary to sacrifice the extensor tendons of the hand, but it has been found practicable, by the exertion of a little care, to save these tendons, and consequently to preserve a more perfect motion of the fingers. The greatest difficulty in operating is met with in cases of rheumatic anchylosis in which the sheaths of the tendons are diseased.

MM. **DEMONS** and **MOURE**, of Bordeaux, reported two cases of

EXTIRPATION OF THE LARYNX.

The first case was one of epithelioma of the base of the tongue and of the upper portion of the larynx. Extirpation was performed, and the patient survived nine months without a return of the disease in the larnyx, though there was a return at the base of the tongue.

The second case was a man, aged fifty-seven, who had had a polyp removed from the left vocal cord one year before. One year after the operation an epithelial tumor appeared upon the right vocal cord. As the ganglia in the neighborhood were not involved, it was determined to operate. Partial laryngectomy was therefore performed. This was done six months ago, and the patient was still alive and free from the disease. The authors believed that the operation promised much in early cases in which there was no glandular involvement.

M. **DUPONT** had performed total extirpation of the larynx once. He had found difficulty in keeping Trendelenburg's tube in position and preferred suturing the trachea to the external wound, bending it so as to shut off the cavity of the larynx.

M. **MOLLIÈRE** had also performed the operation of partial excision once. He had found no trouble from the Trendelenburg cannula. The patient was able to talk by means of the one vocal cord which had been left and an opposing cicatricial band. For cancer of limited extent the speaker thought there should be no hesitation in removing the larynx, in whole or in part.

TUESDAY, MARCH 13TH—SECOND DAY.

The subject proposed for discussion at this session was

THE TREATMENT OF GUNSHOT WOUNDS OF THE VISCERAL CAVITIES.

M. **CHAUVEL** confined his remarks chiefly to wounds of the abdominal cavity. Every penetrating wound, inflicted by small projectiles, of the abdomen, in which there is a probability that some of the contained organs are injured, should, the speaker maintained, be enlarged and explored. The statistics of non-intervention in penetrating wounds of the abdomen show a mortality of eighty per cent. In forty-one cases of laparotomy performed since 1880 for gunshot wounds of the abdomen, there have been twelve recoveries, giving a mortality of about seventy per cent. The earlier the operation is done the more favorable are the chances. If the surgeon wait until peritonitis has begun it is too late, and an operation will be of no avail. There is an additional danger of hemorrhage from a small artery or vein if the surgeon neglect to explore the wound immediately after the receipt of the injury.

M. **DELORME** thought that, while immediate intervention might be advisable in civil practice in the larger cities, it was hardly practicable on the battle-field, or in an ambulance.

M. **PONCET** discussed the question of

CONTUSIONS OF THE ABDOMEN WITH INTESTINAL LESIONS,

caused by projectiles. He traced the various modifications of wounds of this nature depending upon the changes in the nature of the projectiles employed. In former times large round balls were used, which just touched the body, as it were, causing intra-peritoneal effusions of blood. For the past thirty years, however, the tendency had been to the more frequent employment of explosive balls. These caused, not effusions of blood, but intestinal lesions without rupture of the abdominal walls. In the future, he thought, non-penetrating wounds of the abdomen would be less common in military practice than they are now. The new shells, composed of steel, and exploded by melinite, scattered in every direction vast numbers of small ragged pieces with such velocity that they would almost certainly penetrate the abdominal wall, even when they were spent.

M. **RECLUS** regarded the English and American methods of treating these cases as too bold, and he declared himself to be a partisan of armed expectancy. He thought that every penetrating wound of the abdomen was accompanied by intestinal lesions, but he did not agree with the previous speakers who looked upon every such wound as almost certainly fatal. In his experiments upon dogs, he had found that these wounds were relatively of slight gravity. In the treatment of these injuries, he advised firm compression of the abdomen, opium in large doses, abstention from all food except small quantities of iced milk frequently repeated. If peritonitis ensued then, and not till then, he would perform laparotomy, an operation which he regarded as very serious in itself.

M. **LABBÉ** reported a case in which he had performed laparotomy on account of a pistol-ball wound of the abdomen. The patient died in the course of the following night.

M. Verchère read a paper upon

INTESTINO-PERITONEAL SEPTICÆMIA,

following wounds of the gut. It is commonly stated, he said, that death occurs in these cases either from hemorrhage or from peritonitis. The latter is not, however, always manifested by the classical signs of peritoneal inflammation, but may be masked. This form he called

ASTHENIC PERITONITIS.

The symptoms were an abdominal facies, tympanites, an almost imperceptible and rapid pulse, reaching 120 to 150 beats per minute, no elevation of temperature, and an absolute freedom from tenderness of the abdomen, which might even be kneaded without giving rise to the slightest expression of pain. The symptoms of this condition, indeed, are very similar to those of strangulation of the intestine. Moreover, the two conditions are not unlike in their nature, since there is a paralysis of the intestine in these cases which causes obstruction. The treatment should comprise lavage of the stomach, intestinal antisepsis, purgative enemata, and electricity.

M. Castex related four cases of

PENETRATING WOUNDS OF THE CRANIUM,

caused by pistol-balls. In one case there was escape of brain-substance. The wounds were dressed antiseptically, and all of the cases recovered.

M. Panas read a paper entitled

SPONTANEOUS HÆMATOMATA OF THE ORBIT.

He reported a case which was only the fourth instance of the affection on record. It occurred in a child four years of age. The little patient had been subject to epistaxis, but was otherwise healthy and of good antecedents. The other cases had been reported by Fischer, Wharton Jones, and Ziegler.

M. Thiriar, of Brussels, reported a case of

CHOLECYSTECTOMY,

performed upon a lady, aged thirty, who had suffered for six years from colic with jaundice. The operation afforded complete relief.

M. Lannelongue then read a paper on

DERMOID CYSTS IN THE REGION OF THE ANTERIOR FONTANELLE,

in which he endeavored to formulate rules for the diagnosis of these rare tumors. They are congenital, but are not noticed, on account of their small size, until several months or years after birth, when they begin to increase in size. They are fluctuating and usually translucent, are situated in the median line over the anterior fontanelle, and are irreducible. The only treatment is removal, care being taken to dissect away the wall of the cyst. It is better, however, not to operate until the child is about a year old.

M. Ollier had seen three cases of dermoid cysts in this region, one of which was in a man thirty-four years of age. He removed the tumor, leaving the lower wall, which in the course of a short time took on a growth of hair resembling in every respect that covering the rest of the scalp.

M. Polosson related a case of

MALIGNANT PUSTULE.

He removed the lesion with the thermo-cautery, and made multiple incisions in the surrounding œdematous parts. The patient recovered.

M. Leprevost related a case of

PSEUDARTHROSIS OF THE HUMERUS

ollowing a gunshot wound. There was also radial paralysis. As the proximal end of the nerve could not be found in the vicinity of the fracture, the author searched for the trunk in the axilla, and then followed it along until its extremity was seen. The nerve was sutured, but at the end of five months the motion was not restored. The pseudarthrosis was cured by freshening the ends of the bone and suturing them.

M. Berthomier read a paper on the

TREATMENT OF FRACTURE OF THE ELBOW

in children and adults, by immobilization of the forearm in extension and supination.

M. Bilhaut reported several cases of

LATERAL CURVATURE OF THE SPINE,

caused by an unequal growth of the two lower extremities.

M. Cerné read a paper upon the influence of

PHOSPHATURIA

in the production of surgical lesions similar to, but less grave than, those occurring in the course of glycosuria.

M. Verneuil had seen a case of carbuncle in a patient with

DIABETES MELLITUS,

in which, after the cure of the anthrax, the glycosuria gave place to phosphaturia.

Wednesday, March 14th—Third Day.

The order for discussion for this day was

THE RADICAL CURE OF HERNIA.

M. Socin presented a number of statistics, collected from his own practice, showing the results of this plan of treatment. Of 75 cases of reducible hernia, the operation resulted fatally twice; of 85 cases of strangulated hernia, in which the radical operation was performed, there were 11 deaths. Of 133 operations, in which he had been able to follow the patients, there had been 82 cases of definite cure, and 51 relapses.

M. Léonté, of Bucharest, described a new procedure for the

RADICAL TREATMENT OF INGUINAL HERNIA.

After reducing the epiploon with the intestine, he separated the peritoneum for a distance around the internal ring. This becomes wrinkled, and closes the internal opening of the canal. The sac is pulled upon by the left hand while the serous membrane is being dissected away. Then the internal ring is drawn together by a circular suture, the interior of the sac is scraped with a Volkmann's spoon, irritated with phenic acid and chloride of zinc, and then a silver wire or silk suture is passed through the integument and the sac. Of seven cases so treated there had been no relapse at the end of two years and a half.

M. Mollière was strongly in favor of the radical treatment of hernia, and believed that the dangers of the operation were greatly exaggerated. He insisted especially on the necessity of the

EXTIRPATION OF THE SAC.

Of 250 operations the mortality had not exceeded twelve per cent., and this included the deaths resulting from gangrene of the intestine.

M. Lucas-Championnière insisted upon early operation, the earlier the better and the safer, and did not believe in waiting until the strangulation had taken place. It was especially in congenital hernia that the operation gave promise of the best results.

M. Richelot insisted upon the entire safety of the operation in simple hernias of small size, occurring in adolescents and adults. In the case of a very large or a complicated hernia in an adult, the danger of the operation was very slight, but success was less certain than in the first class of cases. In the aged and those debilitated by disease, the benefits to be hoped for from a radical operation did not compensate for the risks.

M. Jules Bœckel related a case of

RADICAL TREATMENT OF UMBILICAL HERNIA.

The patient was a woman, forty-seven years of age, having an umbilical hernia measuring sixteen inches in its long diameter by twelve transversely. The operation was completely successful.

M. Lannelongue reported a case of

RESECTION OF THE LOWER BORDER OF THE THORAX

for the cure of an abscess in a child.

M. Guyon related two cases in which he had operated for

TUBERCULOSIS OF THE BLADDER.

He opened the bladder, scraped the diseased portions, applying also the thermo-cautery, using subsequently injections of iodoform. In both cases the bacilli disappeared from the urine, and in one the cystitis was cured also.

M. Demons read a paper on

CANCER OF UTERUS

treated by vaginal hysterectomy.

M. Terrier reported the results in eighteen cases of

VAGINAL HYSTERECTOMY

for uterine cancer. There were four deaths, three from hemorrhage and one from shock. Three cases were excluded for various causes. Of the remaining eighteen cases there was a speedy return of the disease in seven. The other four were alive and free from relapse at periods varying from over a year to two years and nine months after the operation.

M. Terrillon reported fifteen cases of

ABDOMINAL HYSTERECTOMY

performed for the removal of large fibroid tumors of the uterus. The operation was a grave one, and should be reserved for cases in which the tumor was of very large size and had given rise to alarming symptoms. Ablation of the tubes and ovaries was to be preferred in cases of small or medium-sized fibromata, threatening the life of the patient by repeated hemorrhage.

M. Monod reported a case of

CAVERNOUS LYMPHANGIOMA,

and read a paper on the history and nature of true lymphangiomata.

M. Monod also related a case of restoration of the flexor tendon of the thumb by means of the

TRANSPLANTATION OF A RABBIT'S TENDON.

M. Schwartz reported a case of erectile tumor of the face cured by

ELECTROLYSIS.

The patient was a young woman, one entire side of whose face was disfigured by an enormous erectile tumor. The treatment extended over a period of two years and a half, and had given a very successful result.

M. Redard reported several cases of

ANGIOMATA OF THE FACE,

treated successfully by the same method.

M. Redard also read a paper on the technique of

ORTHOPÆDIC CORSETS,

made of gutta-percha, plaster of Paris, felt, and silicate of potash.

M. Boudet read a paper on the technique of

MEDICAL ELECTROLYSIS,

with special reference to the treatment of erectile tumors.

M. Berrut presented a communication on the diagnosis of

RETROVERSION OF THE UTERUS.

Normally, he said, when the woman is in the standing position, the finger cannot be passed into the posterior cul-de-sac. If this can be done it is an evidence of retroversion.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PRACTICE OF MEDICINE.

Stated Meeting, March 20, 1888.

R. C. M. Page, M.D., Chairman.

Dr. Leonard Weber presented the specimen of aneurism of the thoracic aorta, a brief history of which he had given at the previous meeting, and made some remarks upon the pathology and etiology of the affection.

Dr. J. Weir Roosevelt read a paper (see p. 407) on

PERNICIOUS ANÆMIA.

Dr. Francis Delafield thought that, although during the past few years we had accumulated many more cases of pernicious anæmia, our knowledge of the disease had, instead of growing clearer, become more uncertain. The study of the blood in a variety of other conditions had also become more common, and in them we frequently enough found the condition of the blood which was once considered characteristic of pernicious anæmia. There was the same diminution of the red blood-cells, the same diminution in the quantity of the hæmoglobin—not only in simple anæmia, in Addison's disease, in pseudo-leucæmia, but in a great variety of other conditions. Many patients who had Bright's disease, many who had cancer, many who had phthisis, many whose general health was simply depreciated, but who could not be said to have simple anæmia, had a diminished number of red blood-cells and diminished quantity of hæmoglobin equal to that in the beginning of pernicious anæmia. Thus it had been shown that the lesion which we had regarded as characteristic of pernicious anæmia could no longer be so regarded; nor had we found any other lesion. He doubted whether we knew at all what was pernicious anæmia. He doubted whether we ought to call it a blood disease, or whether we knew what it should be called.

Dr. Kinnicutt said that unfortunately little unanimity of opinion prevailed as to what really constituted pernicious anæmia. On the one hand, it was regarded as a disease *sui generis*, due to some unknown cause, invariably tending to a fatal issue, and without demonstrable lesions aside from blood and marrow changes. On the other hand, it was believed to be a grave or pernicious form of anæmia due to the long-continued operation of causes capable of producing the simpler forms. Recent researches had demonstrated the fact that a group of symptoms, in no way to be distinguished from those present in pernicious anæmia, were due to the presence of an intestinal parasite. On the removal of the parasite recovery rapidly occurred. Again, a similar clinical picture was presented by certain cases, in which extensive destructive lesions of the secretory structures of the stomach were found. In the latter case the question had been raised whether the gastric lesion might not be secondary. From a very careful study of his own cases, which had recently been reported in detail, he was convinced that at least in them this lesion was primary.

Dr. Kinnicutt took exception to the statement that the blood-changes were identical in the simpler and the pernicious forms of anæmia.

The presence of microcytes, megalocytes, and poikilocytes was common to both, although these anatomical forms existed in a much more marked degree in pernicious anæmia. In the latter alone, however, the proportion of hæmoglobin was often *much greater than normal*, almost never less than normal. It had been observed by Laache and others to be double the normal amount. This distinguished it from all other forms of anæmia.

In many cases of chlorosis and simple anæmia it was well known that the percentage of red blood discs was normal, the percentage of hæmoglobin alone being reduced; in other cases the corpuscular richness of the blood was materially diminished, but *not* in proportion to the reduction in the hæmoglobin percentage.

Dr. Kinnicutt was unable to recognize the lesions of chronic gastritis, suggested by Dr. Roosevelt, in the cases of pernicious anæmia reported by him (Dr. Kinnicutt).

Dr. William H. Draper said it had often occurred to him, in studying the physiognomy of patients in hospitals, that a most striking feature was anæmia, and he had thought that if it were possible to discover the mysterious process by which the anæmia was brought about, we should be able to establish a system of therapeutics which would be much more successful than any yet devised. He thought a great deal of confusion had arisen from the fact that we still clung largely to the old classification of primary and secondary anæmia. We knew what secondary anæmia was; it might be, for instance, an anæmia which followed hemorrhage, or a febrile process. We spoke of primary anæmia, the cause of which we could not explain, but the so-called primary anæmia would be recognized as really secondary, could we but discover its cause.

Dr. Draper thought we had arrived at a period when we could adopt a more rational classification, one based upon blood-forming and blood-destructive conditions. For example, he would include all those cases depending upon impoverishment of the blood among anæmias due to blood-destroying processes. They included anæmia from hemorrhage, suppuration, fever—any acute or chronic disease which produced a more or less considerable and prolonged anæmic state. He would include under the anæmias which were produced through defects in the blood-forming function, chlorosis, leucæmias, the anæmia which occurred in chronic Bright's disease, cirrhosis, and the anæmia called pernicious.

Dr. Beverley Robinson had seen more than one case of anæmia in which he had to speculate for some time whether it was or was not one of pernicious anæmia. Time might determine whether it was a simple anæmia, and curable, or a necessarily fatal pernicious anæmia. He would like to have heard something about treatment, particularly by systematic use of oxygen, from which he thought he had derived benefit in anæmia.

Dr. W. R. James thought that if we took the blood changes alone as the basis for classifying pernicious anæmia as a separate disease, as had been done in the past, the classification no longer had firm ground to rest upon, for similar blood changes had been seen in other conditions. We might, perhaps, do better to consider pernicious anæmia only a symptom of a disease, or of a group of diseases, of which at present we knew but little. He had seen a well-marked case of chlorosis in which the percentage of hæmoglobin was sixty or seventy, while in another case, in which the symptoms were less well marked, there was eighteen per cent. of hæmoglobin. As to a classification on the basis of blood-forming and blood-destroying organs, he thought it was not at present practical, because of our ignorance of what were the blood-forming and blood-destroying organs.

Dr. William H. Thomson said he had come to the meeting expecting to have his previously formed ideas of pernicious anæmia made a little more distinct, but instead they had grown more indistinct. Two of the cases which Dr. Roosevelt had described as cases of pernicious anæmia did not, he thought, properly belong in that class of diseases. When Dr. Thomson spoke of pernicious anæmia he had in mind a distinct form of anæmia, characterized by the presence of fever, absence of emaciation relatively to what took place in other forms of anæmia, by the presence of vomiting as quite distinct from gastritis, and by the presence of rectal hæmorrhages, and occasionally, also, by hæmorrhages from other parts of the body. He would be disposed to exclude from among cases of pernicious anæmia one in which there was no elevation of temperature. In pernicious anæmia there was a peculiar lemon-yellow color of the skin and a bright appearance of the fat. He had been struck with the occasional appearance of very small, imperfectly spherical and brilliant red corpuscles, smaller than those of the red blood-cells in the blood. He had regarded them as apparently wandering bodies of pure hæmoglobin. He could not understand how extensive atrophy of the gastric tubules could occur, as had been reported in some cases of pernicious anæmia, without emaciation. Extreme anæmia might be present in Bright's disease, and could be accounted for by the influence of the poisonous elements upon the blood and the gastric changes which took place in this disease; but, although the case might go on to a fatal issue, he would not pronounce it one of pernicious anæmia.

Dr. Kinnicutt said, in reply to Dr. Thomson's question, that in both cases reported by him of pernicious anæmia, in which there was such extensive destruction of the gastric tubules there was both fever and mucous hæmorrhages.

Dr. Roosevelt, in closing the discussion, said he had attempted to state in the paper what had been made so clear by Dr. Delafield, that there was nothing which could be pointed out definitely as the cause of pernicious anæmia; but this much could be said, that the blood lesion was a necessary factor to explain many of the symptoms, and it was, perhaps, well to put a certain amount of faith in a lesion which would do that. He agreed with Dr. Kinnicutt to this extent, that it was possible to have in a simple anæmia, which would recover in a short time under administration of iron, and without any history pointing to pernicious anæmia, a reduction of the red discs to fifty per cent., the hæmoglobin remaining at seventy-five. He knew that in pernicious anæmia there was no necessary excess of hæmoglobin. In some well-studied cases it had been stated that the hæmoglobin was even a little less than the number of discs would indicate. Yet it was a fact pointing to simple anæmia, curable by iron, etc., when there was great reduction of hæmoglobin out of proportion to the reduction in the blood discs.

Regarding blood-forming and blood-destroying organs, he had been unable to learn what they were, and he thought we should not speak of lesions of organs, even the existence of which had not been absolutely proven.

Dr. Thomson had spoken of characteristic color in pernicious anæmia, but it might be absent even in fatal cases. Again, the same pallor might be present in simple anæmia. Then there were cases of pernicious anæmia, in which, as far as the record showed, no fever had been present from beginning to end. Then fever of an irregular type was quite frequent in simple anæmia. Hæmorrhages did not necessarily point to pernicious anæmia. Some observers claimed that hæmorrhage was rare. Then hæmorrhages into the retina occurred also in simple anæmia and other diseases. He could not, therefore, see how we were to distinguish from any one symptom, or group of symptoms, pernicious from simple anæmia, except the whole course of the disease, with its fatal issue, were taken into consideration.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, March 22, 1888.

J. E. Janvrin, M.D., Chairman.

Dr. Grace Peckham read a paper on

WORMIAN BONES IN THE FONTANELLES AND THEIR EFFECTS IN CHILDBIRTH.

Dr. Bullard said he could readily see how, in the specimen presented, the Wormian bone in the posterior fontanelle might prevent overlapping of the sutures.

Dr. Sharlau thought Dr. Peckham overestimated the influence of the Wormian bones. He had known infants to stand the pressure incident to labor for hours, and even two or three days, without destroying life. Long-continued pressure during labor had frequently occurred in German hospitals in women with contracted pelves, without a fatal result to the child. That being true, he could not understand how a little Wormian bone, which might prevent overlapping of the sutures during delivery, would destroy life. The author had said that in all three cases the children were stillborn and the women primiparæ; it was well known that stillbirth was more likely to take place in primiparæ.

Dr. Hall was unable, in a recent case of delivery in a woman with a small, if not absolutely contracted, pelvis, to map out the posterior fontanelle. She was unable to deliver with the forceps, and craniotomy had to be performed. She thought it probable that the posterior fontanelle was occupied by a Wormian bone, as in the case presented by Dr. Peckham.

Dr. Mabbott said that, as resident physician to the Nursery and Child's Hospital, he had not seen a similar case with Wormian bones, but he queried whether their influence would not be, in preventing moulding of the child's skull, to cause damage by increased pressure to the mother's soft parts, and for a similar length of time prove a protection to the child in preventing pressure on the cranial contents. In cases of suspected danger to the life of the child during the second stage of labor, especial attention should be given to the fœtal heart.

Dr. Boldt asked Dr. Peckham in what condition she had found the brain.

Dr. Agramonté, referring to Dr. Peckham's quotation from the old writers to the effect that the Wormian bones were an indication of arrest of development, said it seemed to him that, in the case presented, it showed a new point of ossification, increasing the extent of the whole bone-surface. The skull presented seemed also to be longer than usual in the antero-posterior diameter, which might account for the greater difficulty during the second stage of labor.

Dr. Mitchell asked whether it was always possible to determine the presence of the Wormian bones during labor.

Dr. Peckham closed the discussion, and said it was well known that the infant would stand, during labor, an incredible amount of pressure, but it was usually during the first stage. The physician usually terminated the labor before a long time had elapsed after the second stage. It was not interfered with in the cases related, because the pelvis was roomy, and it was expected momentarily to terminate naturally. The skull was not unusually long, the antero-posterior diameter being but four inches. The bi-parietal diameter was short. The damage from pressure was due, she thought, to its being transferred to the base of the skull where the vital centres lay. They had sought carefully for the cause of death, but the brain had not been examined, as they wished to preserve the skull complete. Regarding the difficulty of determining the presence of the Wormian bones during labor, it was not difficult when one's attention had been called to its occurrence. Whether the sudden pressure and quick delivery with the forceps would not also incur danger was a question.

Dr. W. E. Bullard then reported

A CASE OF PLACENTA PRÆVIA

which occurred in a girl sixteen and a half years of age. About the sixth month hemorrhage began, and the family physician was called, who wrote a prescription, probably for ergotine, and sent for Dr. Bullard. Dr. Bullard arrived about two and a half hours later, and found the patient almost exsanguinated. The mattress was filled with blood; the vagina contained blood-clots. The os was one and a half inch in diameter, dilatable; the head was presenting; the placenta was attached on the left side of the cervix. No pains had yet been felt. As long as the fingers were kept in the cervix the hemorrhage ceased, but recurred when the fingers were removed. Dr. Bullard placed the patient in Sims' position and tamponned with cotton containing alum and carbolized water. After about an hour he removed the tampon, distended the os with the Barnes dilator, introduced the hand, dissected the placenta from the left side of the internal os, and ruptured the membranes, when prolapse of the cord took place. The cord was returned, and, after the arrival of assistance, he applied the forceps to the fœtal head and brought it down upon the perineum, when the cord was again felt, this time pulseless. The child was stillborn and could not be resuscitated. The placenta was expelled at once. The mother made a tedious recovery.

His preference for the forceps in this case was due to the fact that the os was well dilated, the funis had presented, and fear of additional shock which version would cause a very weak patient.

In two other cases of placenta prævia, one being largely of central implantation, the methods employed differed considerably from that which was adopted in this one. In one the hemorrhage occurred near term, was not profuse, labor progressed naturally, the child was stillborn, the mother recovered. In the case of central implantation, hemorrhage took place at the sixth month; Dr. Hanks assisted; the cervix was somewhat rigid, the internal os was close, and dilatation was effected rapidly by egg-shaped rubber dilators; the hand was introduced; the placenta had to be stripped from the left side, a distance of one inch and a half, before the membranes could be reached; podalic version was employed, and two infants were delivered alive; they were kept in an incubator, but one died at the end of three weeks. There was but one placenta, and one common amniotic cavity. The mother suffered somewhat from sepsis.

Dr. H. J. Boldt preferred to employ version to the use of the forceps, as being less dangerous to the mother and fully as safe for the child.

The Chairman related a case similar to that of Dr. Bullard's. The patient had had several miscarriages, and given birth to one child at term, which weighed only about three pounds and a half. It was a breech-presentation, but no difficulty was experienced in delivery. She again became pregnant about two years ago. At about the eighth month she was taken with profuse bleeding. Dr. Janvrin arrived almost immediately afterward, and found the patient nearly blanched; the bed-clothing was saturated; the vagina was filled with clots. The os was dilated an inch and a half to two inches, and the placenta presented. On introducing the finger into the cervix and making pressure upon the child from without, the head could be felt. While the examination continued the hemorrhage ceased. The husband was sent for Dr. Lusk; thorough dilatation was effected by the introduction of the fist into the cervix, which also controlled hemorrhage. The placental attachment was distant from the external os about two and a half inches. The child was dead. Dr. Lusk pressed the child down from without. Dr. Janvrin then experienced little difficulty in applying the forceps to the head and delivering. The slight difficulty arose from a bony projection of the sacrum, perhaps, and exostosis, which had left a furrow on the right side of the child's head. The mother made a good recovery, and had since given birth to a child which weighed a few ounces more than three pounds.

Dr. Janvrin thought that if hemorrhage could be controlled by plugging the os with the hand, it was unnecessary to use any other tampon, and if the patient was not too much exhausted and the cervix could be rapidly dilated, the easiest method of delivery would be to apply the forceps. But even in such a case he knew of no objection to extracting the child by the feet.

Dr. Bullard said, in reply to a question by Dr. Mabbott as to whether in a case of central implantation he would pierce the placenta, that he had had no experience in the matter. In his own case, approaching to central implantation, he was able to pass his finger up, detach the placenta at its attachment to the os, and divide the membranes. He thought it would be difficult to pass the hand directly through the placenta.

Dr. R. A. Murray referred to a paper which he had read before the Section about two years ago, in which he gave the history of a case of absolute central implantation of the placenta. It had generally been stated that in placenta prævia some slight loss of blood was likely to take place, commencing about the fifth month, giving warning of the condition present. There were, Dr. Murray said, a considerable number of cases in which there was no dribbling of blood whatever until labor pains came on, and then the bleeding was likely to be exceedingly profuse. He gave the history of one case of central implantation in which the first hemorrhage took place at term, and the patient very nearly lost her life, so great was the amount of blood lost. He had had two other similar cases, and, in addition to these three, he had seen four other cases of central implantation of the placenta. In lateral implantation he ruptured the bag of waters, which always caused the uterus to contract and check the hemorrhage, giving the physician at least ten minutes to prepare his instruments. He was a firm believer in Barnes' method of delivery in the cases in which there was sufficient time. Most physicians were following the example of Hoffmeyer in proceeding to deliver or bring about abortion at once after discovery of placenta prævia, not attempting to tide the case along to the month of viability. The diagnosis was made in Hoffmeyer's cases after the occurrence of the first hemorrhage.

Adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PRESIDENTIAL ELECTION AT THE COLLEGE OF PHYSICIANS—AN EXPEDIENT IN OPERATING FOR EXTROVERSION OF THE BLADDER—CLINICAL EVENING AT THE MEDICAL SOCIETY OF LONDON—DOCTORS AND THE BUDGET—MR. CROOKES' ADDRESS AT THE CHEMICAL SOCIETY—DISINFECTION OF LONDON SEWAGE—THE HABITUAL DRUNKARDS ACT AMENDMENT BILL.

LONDON, March 31, 1888.

IN accordance with ancient custom, the election at the College of Physicians took place on Monday last, being the Monday following Palm Sunday. About one hundred and fifty Fellows were present and took part in the voting (the members and licentiates of the college have no vote, nor any voice whatever in the management of their college). The method of election is rather peculiar. Canvassing beforehand is strictly forbidden, and even at the time of election candidates are not openly put forward. There is no formal proposing and seconding. The voting is by ballot, and each Fellow present gives his vote for whom he pleases. There may consequently be, as on the present occasion, several Fellows who achieve the unenviable distinction of obtaining a solitary vote apiece. If, as the result of the first ballot, no Fellow receives the suffrages of at least two-thirds present, a second one takes place. At the second ballot a simple majority suffices. On this occasion the issue at first seemed rather uncertain. The first ballot showed that ten Fellows had received votes, more or less numerous, Dr. Quain heading the list. The second one, however, placed Sir Andrew Clark at the head of the poll by a majority of eight (Clark, 79; Quain, 71), and he was forthwith inducted as president. In that capacity I have no doubt he will be as popular as in other positions which he has held. To use a popular phrase, he is a man whom everybody likes. This is no slight tribute for a physician in large practice to receive. Most men who have succeeded very well leave not a few enemies. In Sir Andrew Clark's case I should say they were very few, and he is considered to have the largest private practice of any general physician in this country. Rumor places his professional income at from twelve to fifteen thousand pounds a year. Certain it is that he works hard at his profession. Eight o'clock in the morning, winter and summer, finds him in his consulting-room beginning to see his morning patients. He is often thus occupied till nearly 3 P.M., and then only desists in order to drive round in his carriage to fulfil his numerous out-of-door engagements. With such an overwhelmingly large practice, Sir Andrew has decidedly no temptation to stoop to rob a general practitioner of his patients, as some physicians have been accused of doing. As regards the patients whom he visits at their own homes, I understand that he makes it almost a rule only to visit such patients as have already a medical man in attendance, and refuses to take sole charge of cases.

At the last meeting of the Medical and Chirurgical Society, Mr. G. H. Makins read a paper on a case of extroversion of the bladder on which he had operated. The patient was a boy of five, on whom an attempt to raise a flap by Thiersch's method had failed three years previously. The position of the unsuccessful flap was marked by a cicatrix on the left side of the bladder, which prevented any considerable shifting of the skin on that side. To obviate this difficulty, the sacro-iliac synchondroses were divided on both sides. This allowed approximation of the anterior superior spines to the extent of an inch, with, of course, a corresponding diminution of the gap existing in the situation of the symphysis. This gain was maintained by continuous extension and an attempt, two months later, to unite the opposite boundaries of the bladder. This failed, but at a subsequent operation the bladder was covered by means of a single lateral Thiersch's flap, the exposed surface having been reduced in size from $3\frac{1}{4} \times 3\frac{1}{4}$ to $1\frac{1}{2} \times 1\frac{1}{2}$ inches by the closure of the symphisial opening.

The last meeting of the Medical Society of London was a clinical one, the evening being devoted to the exhibition of cases. Among those shown was a man in whom obliterative arteritis had resulted from the pressure of a crutch. The latter had been used by the patient since the age of eight, but the arteritis was only recent. Mr. Morgan showed a woman, aged fifty-two, who presented a typical example of the disease named by Velpeau "carcinoma en cuirasse." Mr. Rose narrated the case of a man who had received a gunshot injury of the right knee. The joint was opened and cleansed by carbolic and sublimate solutions. A good result ensued.

Doctors are being much exercised in their minds over the proposed horse and wheel taxes in the new budget. It is, however, impossible to keep a cake and eat it as well, and as a remission of a penny in the pound in the income tax is promised at the same time, it is obvious that the Chancellor of the Exchequer was obliged to devise new taxes of some kind or another. The argument that those who use the roads should pay for them is logically unanswerable, and I am afraid that such of our country brethren as wish to avoid the new taxes must take to cycles, a class of vehicles which Mr. Goschen has not ventured to tax. Cycling already counts many votaries among members of our profession, and most English country roads (except in hilly districts) are adapted for it.

At the annual general meeting of the Chemical Society, held a few evenings ago, the president, Professor Crookes, F.R.S., put forward some interesting speculations in his address. It was experimentally proved, he said, that in matter which had responded to every test of an element there were minute shades of difference. The distinction between elements and compounds no longer kept pace with the developments of chemical science, but must be modified to include a vast array of intermediate bodies, meta-elements. If degrees of elementicity were admissible, it would be allowed that chlorine approximated much more closely to bromine than to oxygen, sodium, or sulphur. At the conclusion of his address Mr. Crookes sketched out a theory of chemical energy which, if accepted, completely controverts Sir William Thomson's theory of the final dissolution of the universe through the dissipation of its energy. He conjectured that the heat radiations propagated outward through the ether from the ponderable matter of the universe were transformed at the confines of the latter into the primary essential motions of chemical atoms. These gravitated inward the instant they were formed, and thus restored to the universe the energy which would otherwise be lost to it through radiant heat.

The Metropolitan Board of Works have determined to pursue their system of chemically disinfecting the sewage of London, and have appointed as their consulting chemist Sir Henry Roscoe, F.R.S. Should the Local Government Bill become law, however, the Board of Works will be snuffed out of existence. Not many regrets will probably be felt should such prove to be the case.

It is good news to learn that the Government have given their assent, with certain reservations, to the Habitual Drunkards Act Amendment Bill. Unless crowded out there is, therefore, some hope that the measure may become law during the present session of Parliament.

THE ORAL WHIFF.

To the Editor of The Medical Record.

Sir: If Dr. Otto will re-examine the "oral whiff" as it occurs in his own person, and then re-read Wintrich's and Guttmann's descriptions of "systolic vesicular breathing," I think he will perceive that they are not at all the same thing. The latter is heard by auscultation over "the borders of the lungs near the heart" (Guttmann). I never succeeded in hearing the "oral whiff" in the chest, but only at the open mouth, or along the trachea as far as the sternal notch, where it ceased abruptly. "Systolic vesicular breathing" I have heard in many persons who had no "oral whiff," and I have heard the whiff in persons who did not exhibit "systolic vesicular breathing." The one seems produced at the glottis, the other in the lungs. The one can be heard with the ear held some distance from the patient's mouth; the other is heard only by auscultating the chest. The one is, in my experience, a decidedly unusual, the latter a very common, physical sign.

So far from regarding the "oral whiff" as a pathological phenomenon (if Dr. Otto so understood me), I tried to express the opinion that, even when occurring during repose, it need not necessarily be considered a sign of disease, as Drummond would have us think. At the worst, it seems usually to indicate a nervous heart.

Very truly yours,
William S. Cheesman, M.D.

Auburn, N. Y., April 2, 1888.

"WINTER ITCH," BY A VICTIM OF NINE YEARS' STANDING.

To the Editor of The Medical Record.

Sir: Nine years ago, last December, I left my practice in Michigan and went to New York to study microscopy. In about two weeks after my arrival there I was attacked by intense itching of the skin over the extensor muscles of the legs and thighs. It was so annoying that I consulted the late Dr. Flint, who recommended zinc. sulph., ℈ij.; aqua, ℥ iv., to apply locally, and sol. Fowler, gtt. ij., after meals. In about four weeks it disappeared, and I thought myself cured. Fond delusion! for the next winter, in January, it attacked me with redoubled energy. Some remedies were applied, and in about six or seven weeks it disappeared. It continued, with more or less severity, every winter until 1883, when I again went to New York and for two months had a severe attack. I tried several remedies without apparent relief, and in the spring the "itch" disappeared as usual.

In 1884 I went to Europe, and while in Zürich, Switzerland, was attacked again in the usual manner. I finally went to Vienna, and while there consulted Auspritz and Benedict. Their diagnoses were neuresis. The remedies were Donovan's solution internally, and oleum cadini externally. They were applied for several weeks without relief, and when the warm weather began I got well. In two years I returned to New York, and consulted Dr. George H. Fox, who diagnosed eczema; he prescribed white precipitate locally, and to bathe with Packer's pine-tar soap. This treatment gave some relief. Finally I went to St. Louis, Mo., to live, and the first winter there I suffered more than any year previous. The "itch" began in January, and became so annoying that I could not sleep nights. I would, in fact, in my sleep, so scratch myself that I have frequently had the blood running to my heels. I finally went to Hot Springs, Ark., and took a course of baths for six weeks without relief. When warm weather began I recovered as usual. While in St. Louis and Hot Springs I consulted several dermatologists, who gave varying diagnoses.

This winter it began in December. I then consulted a well-known dermatologist, who said he wished *I knew* what would cure it, for his wife had suffered with it for the past three years. He also asked me if I ever found out a cure to let him know, for which he said he *would be very thankfulindeed.*

While I have been penning these lines a leading practitioner of this city was in my office, and he stated that his wife has the "itch" so badly that she can't sleep o' nights. The claim of one of the writers in The Medical Record of March 3d, that it is due to want of cleanliness, is not well taken. Here are two ladies in the higher walks of life who have had it, one for nine the other for three years. So far as my experience goes, I have never seen it in the lower strata of society.

While in Hot Springs I saw several victims, and they were all persons in the upper social circles.

I have examined it under the microscope, and find nothing but broken epithelial scales and dried blood-corpuscles.

Had I a sufficiently fertile imagination I might have found the bacillus or microbe of "winter itch," and have conferred lasting fame on Kansas City.

The surface has been well *scratched* over, at least in my case, for the last nine years; perhaps if some one should scratch deeper they may find the true cause of the distressing complaint. As it is, we know nothing of its pathology, and as little about its treatment. The writer in The Medical Record has been very fortunate if he has cured all his patients with chrysophanic acid. It had no effect on me, and several others of my acquaintance. I do not believe this disease is contagious. Neither of the gentlemen whose wives have had it have had any trouble.

The only relief I have experienced from remedies is a saturated solution of chloral hydrate applied with a brush. It cauterizes the skin. For the time being you have converted an "itch" into a burn.

Acid. carbol., ʒ j.; aqua, ℥ j., has given temporary relief. It is a milder cautery than the chloral. That there is here a grand field for some aspiring dermatologist no one who has ever had the "itch" will for a moment doubt.

Le Roy Dibble, M.D.

1100 Main Street, Kansas City, March 24, 1888.

An Appreciative Guest.—We have received a communication from Dr. A. Kallay, of Carlsbad, editor of the "Illustrirter Aerztlicher Almanach," in which he desires to express, not only his admiration for the many evidences which he saw here of culture and of medical and scientific progress, but also his thanks to all whom he met while in this country, for their uniform courtesy and kindness to him. He proposes to write an account of the physicians and medical teachers of the United States, as well as of what he saw, and was impressed with, in this country, as soon as his duties will afford him the necessary time. "But at the present," he says, "I only desire to express my thanks for the extraordinary hospitality I have enjoyed in so many instances, as it is a physical impossibility for me to thank individually each one for the kindness I have received at his hands. With the hope that in Carlsbad an opportunity may present itself to enable me to balance accounts of hospitality with my American friends, I wish them all farewell."

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 25 to April 7, 1888.

KIMBALL, J. P., Major and Surgeon. Granted leave of absence for two months, to take effect about April 10, 1888. S. O. 68, A. G. O., March 23, 1888.

CROSBY, W. D., First Lieutenant and Assistant Surgeon. Granted leave of absence for two weeks. S. O. 29, Department of Arizona, March 16, 1888.

AZFULL, Thomas F., Captain and Assistant Surgeon (retired). Died March 12, 1888, at Fort Lee, N. J.

BAXTER, Colonel JEDEDIAH H., Chief Medical Purveyor; Major CHARLES R. GREENLEAF, Surgeon; detailed as members of an Army Retiring Board appointed to meet at Washington, D. C., on Wednesday, April 4, 1888. S. O. 75, A. G. O., April 2, 1888.

ALDEN, CHARLES H., Major and Surgeon. Will repair to Washington, D. C., on public business, and on the completion thereof will return to his station (West Point, N. Y.). S. O. 75, A. G. O., April 2, 1888.

BIART, VICTOR, Captain and Assistant Surgeon. Having been found incapacitated for active service by an Army Retiring Board, sick leave of absence is still further extended until further orders on account of disability. S. O. 77, A. G. O., April 4, 1888.

GARDNER, EDWIN F., Captain and Assistant Surgeon. Leave of absence extended fourteen days. S. O. 77, A. G. O., April 4, 1888.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 7, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	2
Scarlet fever	145	21
Cerebro-spinal meningitis	7	7
Measles	57	4
Diphtheria	125	28
Small-pox	25	4
Yellow fever	0	0
Cholera	0	0

LAWSON TAIT'S METHOD IN PLASTIC OPERATIONS.—Dr. C. W. Oviatt, of Oshkosh, Wis., writes: "In the issue of THE MEDICAL RECORD of February 11th, appears a communication from Dr. T. Griswold Comstock, of St. Louis, under the above heading. While indorsing all that he says in favor of the method and of its superiority over older ones, I am surprised that he is unable to learn of anyone practising it in this country, excepting himself and a homœopathic professor. Professor A. Reeves Jackson has taught this method, and performed the operation at his clinics at the College of Physicians and Surgeons of Chicago, for the past four or five years. Instead of silk, Professor Jackson uses silkworm-gut sutures, the advantages of which can be readily seen. As stated by Dr. Comstock, the technique of the operation is difficult to comprehend from a written description, but becomes sufficiently easy when once witnessed, and I feel sure that many other former pupils of Professor Jackson besides myself are performing the operation successfully whenever cases of perineal laceration, requiring an operation, present themselves. The same principle is successfully employed in operations upon single hare-lip. The edges of the fissure being split, the mucous membrane is united by one row of sutures and the skin by another. No tissue is lost and a minimun cicatrix results."

ONE CURIOUS AND INSTRUCTIVE STORY OF DR. DARWIN, Charles Darwin's father, is worthy of reproduction. He was once called in consultation to see a serious case, which the regular attendant had pronounced hopeless; Dr. Darwin saw the case, gave some hope of recovery, and went his way. The patient died, and Dr. Darwin felt sure his reputation in that household was gone forever. Not long afterward, to his great surprise, he was again summoned to the same family, and found that gratitude, and not resentment, had been felt toward him for encouraging a hope which had nevertheless proved without solid foundation. He was accustomed thereafter to say that practitioners should be very slow to stifle hope, as such a course both paralyzes effort and brings, before its time, the bitterness of death.—*The Lancet.*

IRON IN PURPURA.—A chemical examination of the blood, bile, pleuritic effusion, brain, liver, spleen, marrow of the bones, kidneys, lungs, and lymphatic glands, in a case of purpura, has been made by Dr. Zaleski, and published in the *Russian Military Medical Gazette*, his object being to determine whether this disease, which is called by him "morbus maculosus Werlhofii," is associated with any increase in the quantity of iron in the body, as some results, obtained by Hindenlang and Kunkel, appear to indicate. Dr. Zaleski found that, so far from this being the case, the iron was diminished by something like a half. He found no inorganic iron compounds like those described by Kunkel, but most of it existed in the form of an albuminate; some, however, was found in the pigment spots in very stable compounds similar to hæmoglobin. More iron appeared to exist in the gray than in the white substance of the brain.—*The Lancet.*

TO REMOVE WATER FROM ALCOHOL.—If gelatine be suspended in ordinary alcohol it will absorb the water; but as it is insoluble in alcohol that substance will remain behind, and thus nearly absolute alcohol may be obtained without distillation.

FOR ORTHOPNŒA, due to defective heart action, free purgation, with the hourly administration of digitalis and nux vomica, are recommended.

PHYSIOLOGICAL VARIATIONS IN THE POSITION AND SHAPE OF THE LIVER.—At a recent meeting of the Medico-Chirurgical Society of Edinburgh, Dr. J. Lymington made some remarks on this subject. He said (*The Lancet*) that the ordinary text-book description of the liver was incorrect. This fault was due to the fact that the organ was usually described as if it were a flat organ. To get a proper idea of the shape of the liver *in situ*, they must build one up after the manner of His, whose model he showed. This model he believed to be fairly correct, and his conclusion had been drawn from the examination of a very large number of frozen sections. The Spigelian lobe and the depression for the vena cava inferior, which were usually described as on the under surface, were really situated anteriorly. It was best to consider the liver as possessed of superior, right, left, interior, anterior, and posterior surfaces. Within physiological limits he had found that the position of the liver varied greatly. Probably the most important factor in this alteration was the stomach, according as it was full or empty. This would be appreciated from the position of the viscus. He had found experimentally (that is, on the dead subject) that with increasing distention of the stomach the left edge of the stomach became depressed, and the longitudinal fissure moved to the right. The suspensory ligaments acted as a kind of check rein. When the stomach was empty it was folded back on itself, but when the stomach was full it was stretched, as its attachment to the longitudinal fissure moved to the right. He did not know how far the matter had been investigated clinically, but he had no doubt as to the results as obtained on the dead subject.

WASTED SUNBEAMS—UNUSED HOUSE-TOPS.

BY GOUVERNEUR M. SMITH, M.D.,

NEW YORK.

HUMAN habitations, though erected for the benign purposes of insuring comfort, affording protection, and promoting family privacy, are, unfortunately, often the causes of a number of the morbid ills from which mankind suffer. This fact is true, as relating to the residences both of the rich and of the poor. It is a difficult task to construct an absolutely sanitary dwelling. In nearly every home, however, there are more or less avoidable, insalutary conditions, which are undermining the health of each family circle.

Tent-life, in genial climes, affords to many a healthful mode of living; and tent-life, in the warm season of the temperate zone, has its fascinations and its beneficial results. To be tabernacled under canvas and engaged in open-air occupations is often healthful; but the camp must be well sited, or the proximity of unkind neighbors, as cesspools, fens, and polluted water, will as surely rob the camp-dweller of his vitality as the footpad will rob the unguarded of his treasures. Camp-life, salutary as it may often be, is not adapted, from climatic and other causes, to meet the necessities of universal home requirements.

History tells us that certain nomadic tribes, in the early ages, finding aggregation and permanency of residence desirable for business and other purposes, built solid structures, and, striking their tents, have thenceforth dwelt in substantial residences. From these primitive architectural styles of dwellings, we can learn certain lessons which, if adapted to suit our own civilization and our own climate, would promote the health and longevity of our race.

The nineteenth century will ever be memorable for the advancement it has given to medicine, surgery, and sanitary science; but the twentieth century, when reviewing and profiting by the achievements of its predecessor, will doubtless be amazed that the domiciles of mankind, especially in cities, were in some respects inferior to those built several thousands of years previously.

The writings of Virgil, Horace, and other classical writers can be read with interest and benefit, at the present day, as teaching the style and erudition of an ancient period. In Xenophon's "Memorabilia," after describing how homes should be pleasant and useful, cool in summer and warm in winter, it is added: "If it is well, therefore, that houses should thus be made, ought we not to build the parts toward the south, higher, that the sun in winter may not be shut out, and the parts toward the north, lower, that the cold winds may not fall violently on them?"

Sacred writers offer important lessons, also, concerning Eastern habits of thought and customs regarding habitations, which can be utilized in a most profitable manner in the present age. The early Oriental had no conception of the nature of air or sunlight, as now understood by modern science. Probably much of our present knowledge is but polished ignorance. Chemistry and physics have only recently become efficient handmaids in the precise examination of nature, but without these aids the Eastern mind drew certain broad and grand deductions from the investigation of natural phenomena. Some of these tenets are axioms in our own philosophy.

These ancient forefathers believed that fresh air was an important factor in maintaining physical vigor, and that exposure to the solar beams was salutary, and they lived according to their convictions. In constructing their homes their architects utilized their house-tops and gave them salubrious plateaus. The roofs, gently declining as water-sheds, were covered either with tiles, bricks, or cement, making them as durable as pavements. Beddings of turf, prettily distributed, made these artificial deserts to blossom as the rose.

The boundaries of each house were designated by walls, but it was possible to walk over an extended neighboring area. To prevent accidents, obedience was given to the scriptural injunction, "When thou buildest a new house, then thou shalt make a battlement for thy roof, that thou bring not blood upon thine house if any man fall from thence." It is not a matter of wonder that such house-tops proved favorite places of resort, for worship, conference, and repose, and that occasionally tents were spread upon them.

Is there anything either in our climate or state of civilization which prevents us from, in a measure, imitating such ancient, useful, and fashionable airiness? During the inclement season of the year, comparatively little use might be made of the house-tops. I will subsequently allude to how the upper stories of dwellings might be constructed to catch the genial sunbeam, while shutting out winter's rudeness. Our atmosphere is proverbially bright, and many of the severer days are sunshiny; the genial element is subject to capture and benign use, as we can pluck quinine from its barky surroundings.

In a great metropolis like this, there are thousands of children and invalids, to say nothing of those in mature years and engaged in the ordinary pursuits of life, who require more fresh air and sunning, than is now practicable. City yards are small, shut in by tall buildings and high fences; the parks may not be adjacent, and the streets afford ill-conditioned pleasure-grounds.

Cannot architectural ingenuity, coached by sanitary science, contrive some method of using the thousands of acres of house-tops on this island so that roofs, now so useful in affording in-door protection from cold, sleet, and rain, can be made additionally useful, at certain seasons, by affording out-door recreation and protection from invalidism? Cannot the same skill contrive new designs for the upper and most salutary stories of our dwellings; playing rooms and sunning rooms, especially adapted for the winter season, but so cleverly fashioned that too intense torrid beams can be excluded in summer?

The "solarium" of the New York Hospital, made attractive with its plants, birds, and aquaria, is a potent ally of therapeutics in restoring the convalescents, and at the Hospital for the Relief of the Ruptured and Crippled, the contagious sparkle of the sunbeam is found shining in the eyes and lives of the young patients.

Physicians not infrequently have occasion to observe the arrangements and conditions of the upper floors in our first-class private dwellings; for if a servant is sick, the family physician may be summoned to attend. The conditions may not be absolutely pernicious, but the space on these precious stories might be utilized in a much more healthful and attractive way. The heated and vitiated air from the lower part of the house rises to the top floor, with perhaps slight provision for its exit, and here are found servants' and storage rooms and also often a dark closet with precipitous ladder, leading to the scuttle, rarely entered and ascended, except by workmen to repair the roof. Apartments for domestics, have to be provided for, but quarters for trunks and unused articles, rather than occupying choice space, could be centralized in the building, be lighted from above, or relegated to some special annex in the yard.

In the ordinary and more spacious private dwellings the upper floors could be revolutionized: ventilating shafts introduced, new broad windows running the width of the house both front and rear, rearrangement of space, ready accessibility to the roof afforded, and at least a part of these floors made attractive to children and invalids as a bright, airy, and healthful resort. The limits of this article forbid giving details of such construction, and other collateral suggestions, making such changes practicable.

It is beyond the scope of this paper to point out all the evils attendant upon modern homes; one evil to which I am specially alluding is that of etiolation. Etiolation, while favorably regarded by farmers in rendering celery white, crisp, and tender, is not favorable in regard to bringing up human beings.

Not many years ago, for a time, it was widely customary here, to hang blue-tinted glass panes or sashes in windows, curtains were drawn back, and many a room, from which the winter's sun was ordinarily, for the most part, excluded, was now brightened. Invalids and others basked in the shiny genial, and apparently with benign effect. Was such effect attributable to the mere azure tint alone, or to a salutary and unaccustomed hyemal basking?

In many of the lofty and palatial apartment houses in New York, comparatively fireproof, wealth selects suites of rooms near the apices, the air being dryer, purer, brighter, and healthier than near the ground. It seems very clear that even private dwellings, occupied by single families, are not planned in the wisest manner.

Equally new attention should be paid to a utilization of the roof for a large part of the year. The city boy of today wishes to fly his kite. As a special privilege, parental consent is given to his going upon the house-top; but, with what injunctions! Precautions against falling off, that he take feline steps, or the paint will be scratched and the joints of the thin tin covering will be cracked and the roof made leaky, etc. As illustrating present inaccessibility to the roof: during the recent large fire at Forty-second Street and Lexington Avenue, a party of ladies in one of the fine houses on Murray Hill endeavored to go on the roof, to witness the adjacent conflagration. One of the ladies became wedged in the narrow passage. She survives, to grace her family, and to tell a humorous experience.

Roofing can be contrived suited to this climate, and enduring as pavement. A pleasure-resort might ornament each residence, its limits bounded by the area of the dwelling; neighborly consent could widen the range, turf and flowers brightening the plain. Iron-framed and glass-enclosed rooms, or cupolas, could be added, which would prove useful during all seasons, artificial heat tempering brumal inclemency.

If such adaptation of house-tops would be an advantage to the affluent, who can escape city life during the summer, how much greater advantage would be secured to the tenement-house districts. It would be more difficult to preserve roofs in the latter quarters in good order, but the public weal seems to demand that ingenuity should devise an adamantine roof-covering. The promiscuous mingling on house-tops of the residents of slums, freed from police restraint, might at times lead to mischief; but ordinarily, and over a large area, it is reasonable to believe that the innate proprieties of life would prove an all-sufficient constabulary influence. For the higher grade of tenement houses, such fresh-air facilities would probably be hailed with delight by the inmates. The proximity of open breathing places to their rooms would endear their humble homes. Summer moonlight evenings could have a new aspect; and, again, round a family lantern, groups might gather to read, sew, or engage in games, and thus a home-felt pleasure could quiet restless spirits, craving questionable or illicit amusements. More true enjoyment might be observed in such groups than on the piazzas of fashionable resorts. Landlords could arrange for the periodical sweeping of roofs, as well as the halls and stairways, and, among a very large class of the respectable poor, pride would stimulate to a tidy and decorative care of their home parks.

The confirmed vicious and degraded classes would neither appreciate nor properly use such improvements if offered them. In turning to higher grades of humanity, we find an aristocracy permeating even the lower million. In the same tenement house social distinctions may be observed among families, obstructing intimate domestic intercourse and cordial friendly co-operation; but a well-recognized common weal would doubtless link such diversities into a sufficiently harmonious and democratic unity of action.

I have thus pointed out what advantages to health might be secured by a rearrangement of the upper stories of private dwellings, making them the most salutary, in each residence. I have also shown how the house-tops of both the opulent and of the poor might be adapted for the private and public welfare of mankind, especially in cities.

Architects have merely to study ancient history and modern science to utilize the suggestions here made. Sunbeams and oxygen have been running to waste long enough. People must congregate into cities, and such crowding together must necessarily preclude, in a measure, some of the most salutary ways of living. The poet has said, "God made the country, and man made the town;" but the Divinity who so beautifully fashioned the country, brightens both His own handiwork and the town with the same sunlight, and aërates with the same atmosphere.

Cannot cities more generously use nature's benign gifts? Cannot the closing years of the nineteeth century witness a revolution in the construction of dwellings, a change in the habits of city life, and a most notable improvement in the health of the people?

THE SOLUBILITY OF MEAT.—Dr. N. Pavlovski, who has just published a number of experiments made in Professor Dobroslavin's laboratory, in St. Petersburg, on the solubility of meat in water, finds that by means of a temperature of 302° F.—under high pressure, of course—water will dissolve one and a half times as much of the albuminoid constituents of meat as when the meat is boiled in it under ordinary circumstances; also that the addition of a small quantity of hydrochloric acid increases the amount dissolved to a very marked degree, so that he succeeded in obtaining a solution containing as much as sixty-four per cent. of the meat. This was effected by boiling for eight hours in a digester, at a temperature of from 300–320° F., meat and water to which had been added some dilute hydrochloric acid containing ten per cent. of the gas, or nearly the same proportion as the B. P. preparation. Without the acid, only about sixteen per cent. of the meat albumen dissolved. Some further experiments were made—to ascertain the proportion of acid most favorable to the solution. One or two cubic centimetres, added to eighty cubic centimetres of water, were found to dissolve much more of the meat than a larger proportion of acid. Thus, with eight cubic centimetres of the acid, only fifty-three per cent. was dissolved, and with fifteen cubic centimetres, only forty-eight per cent. A similar effect is observed in gastric digestion, where too large a proportion of hydrochloric acid arrests digestion, and the process can only be made to recommence by the neutralization of part of the acid.

YELLOW HAIR.—This was esteemed a beauty in the time of the Plantagenets, when ladies used saffron to dye it. Queen Elizabeth made yellow hair fashionable. Her yellow hair was "fair atired with rich strings of golden wire. And gold wire was abouten all her genteel middle small."

UMBILICAL TUMOR IN AN INFANT FORMED BY PROLAPSE OF THE INTESTINAL MUCOUS MEMBRANE OF MECKEL'S DIVERTICULUM.[1]

By L. EMMETT HOLT, A.M., M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK INFANT ASYLUM, NEW YORK.

A WELL-NOURISHED female infant, aged seven months, was referred to me for treatment by my friend, Dr. R. C. M. Page, for an umbilical tumor. On examination, there was found a bright red mass, one-fourth of an inch in diameter, and projecting nearly three-fourths of an inch from the bottom of the umbilical cicatrix. It was cylindrical, slightly rounded at its extremity, and pedunculated at its cutaneous attachment. Its surface resembled mucous membrane; it was perfectly smooth, shining, nowhere granular. At one point, where the epithelium had been rubbed off, there was a little capillary hemorrhage. The mass was solid, did not protrude more upon coughing or crying, and no opening could be found anywhere in it.

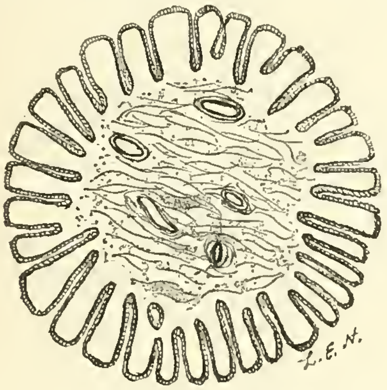

FIG. 1.—A schematic drawing of a cross section of the tumor, giving the relations of the parts and the general appearance under low power.

The following history was given by the mother: The cord fell at the sixth day, but the umbilicus did not heal completely for six weeks; once a hemorrhage took place sufficient to wet a place in a napkin, the size of one's hand. The tumor was first discovered about this time (sixth week). It was then quite small. Since that time it has slowly but steadily enlarged until its present size was attained; this in spite of various astringent and caustic applications, compresses, bandaging, etc. There had been a little watery discharge, tinged with blood at times, but nothing resembling fæcal masses, or with a fæcal odor, had been observed.

The tumor was drawn well forward with forceps and a silk ligature tightly applied about its base. It was then snipped off with scissors and the stump touched with the cautery. The ligature fell off in four or five days, and when the patient was last seen, about a month after the operation, no trace whatever of the tumor could be detected.

Dr. Ira Van Gieson, Assistant at the Pathological Laboratory of the College of Physicians and Surgeons, made the following report upon the specimen.

Microscopical examination.—"The nodule consists of two portions, an outer peripheral zone, and an inner central portion. The outer zone contains long follicles (Fig. 2, a), having a membrana propria, and a lumen lined by cylindrical epithelial cells, among which are a few scattered beaker-cells. The tissue between the follicles consists of smooth muscle-cells, and of small spindle-shaped and small spheroidal cells. The free border of this zone has a number of thin-walled vessels greatly distended with red blood-cells; in places the red blood-cells have escaped from the vessels and form degenerating, diffuse, pigmented, brownish-red masses. There are apparently commencing necrotic changes in this free border, for it stains badly, and its histological elements are indistinct and partly converted into amorphous areas.

"The central portion consists of scattered interlacing bands of smooth muscle-cells, which enclose areas of rather loose, moderately vascular, fibrillar connective tissue, containing here and there large blood-vessels. At the bases of the follicles the smooth muscle-fibres form, in places, a fairly distinct band, corresponding to the muscularis mucosæ (Fig. 2, b). Beneath this rather ill-defined muscularis mucosæ, are occasional isolated, circumscribed collections of small round cells—apparently the solitary follicles of the small intestine.

"It would seem, then, from its morphological characteristics, that the nodule consists of a portion of the mucosa and muscularis mucosæ of the small intestine, the latter being mixed with a moderate amount of new-formed connective tissue."

Scattered through medical literature for the last fifty years are the records of quite a number of cases of umbilical tumors in young infants, with clinical features much like the case reported. They are mentioned by Holmes[1] as "warty or nipple-like tumors," which seem due to some morbid condition left by the separation of the cord.

Holmes quotes Athol Johnson, who, he says, first described them in English as, "short nipple-shaped tumors or papillæ rising from the centre of the main umbilical depression, sometimes to the height and circumference of an inch. In some cases a minute canal extends a short distance into them, but no urine escapes. They are easily cured by ligature."

The microscopical character of these tumors was first accurately described by Küstner.[2] He gives a detailed description of two cases, with drawings of the appearances, which so closely resemble those of the case reported that they might have been made from the sections.

Küstner drew a sharp line of distinction between these cases and simple umbilical fungi. Examinations were made of seven cases of the latter variety; they were found to be made up of ordinary granulation-tissue. They differ further, as he pointed out, from the "nipple-like tumors," in that they are only seen during the first few weeks of life; that they develop quite rapidly; that they have no definite size or shape; that they are usually quite easily repressed by caustics, and but little hemorrhage follows their removal.

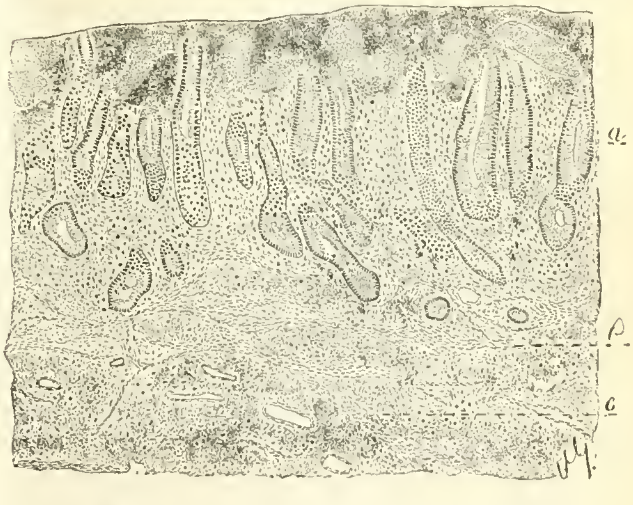

FIG. 2.—*a*, Mucosa with a partially degenerated free border containing masses of extravasated blood; *b*, muscularis mucosæ; *c*, areas of new connective tissue containing large blood-vessels and scattered bands of smooth muscle fibres. × 80

The other tumors develop very slowly, some scarcely changing in size for months; their shape is characteristic; they may be seen in children aged several months (seven months in the case reported); caustics have little or no effect; quite large hemorrhages are not uncommon after section. Küstner has given them the name *adenoma.* He admits that the surface of the tumor corresponds in all respects with the mucous membrane of the intestine. Having examined the umbilical cord in a number of cases, at different distances from the body, and finding no trace of any such tissue elements, he inclines to the view that the starting-point of the new-growth is an inclusion in the umbilical cicatrix of some epithelial cells, the remains of the omphalo-mesenteric duct, or Meckel's diverticulum.

[1] Presented to the New York Pathological Society, December 14, 1887.

[1] Surgical Diseases of Children, p. 181, 1869.

[2] Virchow's Archiv, Bd. lxix., 286.

The name "adenoma" seems to me to be an unfortunate one, as being at the same time, both misleading and inexact. It seems more logical to regard the tumors as produced by an inversion or prolapse of the mucous membrane of an open diverticulum, since there are other umbilical tumors like these, in that they are covered with intestinal mucous membrane, which admit of no other satisfactory explanation. These have been very fully described by Barth,[1] and will be considered later.

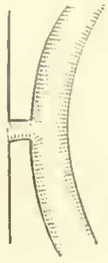

FIG. 3.

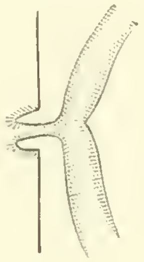

FIG. 4.

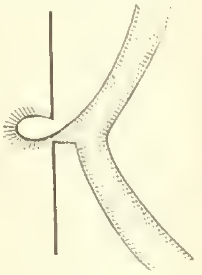

FIG. 5.

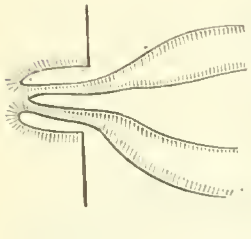

FIG. 6.

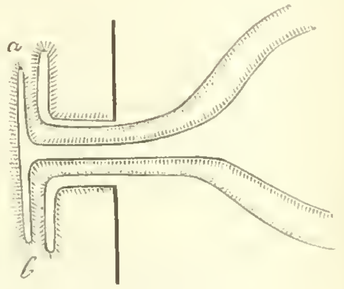

FIG. 7.

These drawings, except Fig. 5, are from Barth.

Meckel's diverticulum, according to Birch-Hirschfeld,[2] is to be regarded as an arrest in development of the bowel in one of its steps, where it is in connection with the umbilical vesicle. In the most marked degree there exists a fissure in the abdominal wall below the navel, through which the ileum opens. Through this opening the fæces pass, the bowel below being very narrow or rudimentary.

In the next grade, the ileum communicates directly with the abdominal opening at the umbilicus by means of the patent omphalo-mesenteric duct; the bowel below may be open and well developed.

In a third class, the ventral fissure is closed and a blind process of the ileum exists, attached to the umbilicus by a fibrous cord, the remains of the obliterated duct.

Lastly, in the slightest grade there remains from the duct only the free diverticulum of the ileum.

It is with the second variety that we are chiefly concerned.

Fig. 3 represents a simple open diverticulum, giving a fæcal fistula at the umbilicus. These cases are not so very rare. King[3] reports two such, in which autopsies were made, death having occurred from other causes. In both a diverticulum was found which communicated with the ileum from ten to twenty inches from the cæcum.

Several instances[4] are on record in which intestinal worms have been discharged through such fistulæ, one[5] in a child seven years of age, the opening dating from birth.

In the next class of cases there exists an umbilical tumor with a fistula at its summit. From the fistula, fæcal masses are discharged as in the former variety, and a probe passes into the abdomen some distance, presumably into the intestine.

These tumors are covered with mucous membrane which the microscope shows to be like that of the intestine. Barth represents their formation by Fig. 4, the relation of which to Fig. 3 will be apparent at a glance. He has collected six cases like this. I have been able to find two more.[1]

Closely resembling these cases is one reported by Pearce Gould[2] as a "Congenital Mucous Polypus of the Umbilicus." This tumor was in all respects like the preceding class, except that the central opening existed only to the depth of an eighth of an inch, or rather a probe passed no further. Having made the "microscopical examination and found the tubular glands upon the surface lined with columnar epithelium," he settles on the diagnosis of polypus, and compares the case to congenital rectal polypi, remarking that "it is probably a safe conjecture that it originally developed from embryonic tissues, the remains of the umbilical vesicle."

Deferring for the present the consideration of the relation of this and those preceding it, to the one reported at the beginning of this paper, we pass to the cases represented by Barth, by Figs. 6 and 7, where there is not only an inversion of the mucous membrane of the diverticulum, but prolapse of the intestine.

In cases represented by Fig. 6 there is a conical tumor with a single external opening, dividing into two at a little distance from the surface. In Fig. 7 there is a tumor, pedunculated at its base, but broadening out, terminates in two cornua, at both of which are fistulæ, which lead inward for a considerable distance, but which do not intercommunicate.

Barth has collected six cases belonging to the class represented by these two diagrams, and adds one of his own, making seven in all. Four presented the two-horned tumor. I have been able to find but two other cases on record to add to his list. Gibb[3] records a case which is remarkable. The tumor projected two inches from the truly body. The child was premature (seven months), and died on the ninth day. Meconium had escaped meanwhile from one of the fistulæ, but not from the other. The autopsy showed the colon to be reduced to the size of an ordinary round worm, but pervious. One of the fistulæ led into the intestine, the other admitted a probe only to the depth of three-fourths of an inch. No microscopical examination was made, but the tumor was considered an inverted colon, the pervious opening being regarded as the ileo-cæcal valve leading into the ileum, and the one patulous a short distance, as the vermiform appendix.[4] The other case is from Holmes (*loc. cit.*), and resembles in many features Gibb's case, though not so typical. This protruded inside the membranes, covering the navel, while Gibb's case projected alongside of it.

In all of the cases mentioned the tumor has been covered with mucous membrane. In every instance in which microscopical examination has been made this has been found to be intestinal mucous membrane in all its essential features. The pathology of all these tumors seems to me to be the same, whether they are accompanied by a fistula or not. This feature is one of secondary diagnostic value. Admitting that the cases represented by Fig. 7 are due to inversion and prolapse of the intestine through a diverticulum, and this point seems to be demonstrated, we must, I think, accept the same view of the tumors with no opening.

[1] Eves (Lancet, 1845, i., 101) describes a red, fungus-like tumor, the size of a raspberry, in a child one month of age. In the centre of it was a fistula from which fæces were discharged. A probe passed in two inches; cured by ligature. The second case, by Pratt (Lancet, December 27, 1884), is very similar.
[2] London Pathological Society Reports, xxxii., 204.
[3] Ibid., vii., 216.
[4] In the report is given a beautiful colored plate showing the tumor and its relations.

Two explanations may be offered for them. The case reported by Pearce Gould showed an opening for a short distance only; others have been recorded like it. Fusion of the two internal mucous surfaces appears to have taken place in the neck of the tumor (*vide* Fig. 4), but not at the orifice. In the solid, nipple-shaped tumors this process may have been complete, so that the central canal of mucous membrane is entirely obliterated.

The other hypothesis seems rather more plausible, *i.e.*, that at one margin the mucous membrane is inverted, while the attachments of the other margin to the abdominal wall prevent this inversion from taking place. I have drawn Fig. 5 to illustrate how this might occur. This would produce a conical or cylindrical tumor, covered with mucous membrane, without an opening, complete or partial.

The whole subject may be briefly summarized as follows: There occasionally exists an abdominal fistula at the umbilicus in connection with Meckel's diverticulum. When this opening is large, prolapse of the intestine may take place through it, forming a congenital tumor of considerable size. With these larger tumors are usually associated other malformations of the intestine, generally a rudimentary colon. The tumor may project into the funis or alongside of it. Of the nine cases on record one was not followed up, but all the other eight were fatal, whether operated on or not, mainly for anatomical reasons. The patients have died so early that there was no opportunity to observe whether there was any tendency of the tumor to increase in size.

The features of these cases are such that they can hardly be mistaken for anything else.

The small tumors are generally not seen till the cord has fallen off. A slow increase in size has been noticed in most of the cases long under observation. They are conical or cylindrical in shape, and rarely project more than an inch. They differ from the large tumors in that only the mucous membrane, with sometimes part of the submucous layer, is prolapsed.

Whether a fistula is present or not, makes no essential difference in pathology, prognosis, or treatment. They are not usually associated with other malformations, grow slowly when left to themselves, but are readily cured by ligature.

They are to be diagnosticated from simple fungous growths by their shape, their smooth mucous surface, their persistence, and, most of all, by their microscopical characters. Microscopically, these do not merely suggest intestinal mucous membrane, but they represent that structure in all essential features. Hence the terms adenoma, mucous polypus, etc., which have been applied to those without an opening, are not appropriate.

5 East Fifty-fourth Street, New York.

How Dr. Oliver Wendell Holmes Discovered the Secret of the Universe.—Some of our readers may not have read of Dr. Holmes' interesting description of how he one day solved the enigma of creation. Having observed that when unconsciousness is consciously approached, as during the inhalation of an anæsthetic—when the mind is on the confines of two worlds—there arise sublime and voluminous, but fugacious thoughts, and having satisfied himself that in these thoughts, if they could only be caught and transcribed, there lay enshrined the secret of the universe, he determined that by a supreme effort of the will he would catch and transcribe them; so, placing himself in his arm-chair, with pen, ink, and paper at hand, he inhaled the vapor of chloroform. As drowsiness stole over him, and just as unconsciousness was impending, those sublime and marvellous thoughts arose, and by a vigorous effort he seized his pen and wrote, he knew not what, for before he had finished he fell back unconscious. When he awoke, with trembling anxiety he turned to the sheet of paper, on which he could read, in scrawling characters but quite legible, the secret of the univers, written in the words: "A strong smell of turpentine pervades the whole."

AN ATYPICAL CASE OF THOMSEN'S DISEASE (MYOTONIA CONGENITA).[1]

By C. L. DANA, A.M., M.D.,

NEW YORK.

Thomsen's disease, or myotonia congenita, is defined by Erb as a disorder of hereditary or family type, beginning in childhood and more pronounced after adolescence, characterized by the occurrence after rest, and during voluntary movement, of a tonic contraction of the muscles, which lasts for a few moments and then gradually disappears. In connection with this is some muscular hypertrophy, accompanied by a *decrease* in muscular power. The muscles also show peculiar mechanical and electrical irritability. The disease is chronic and not fatal. It is, in fact, a primary defect rather than a morbid process.

Of the cases reported under the head of Thomsen's disease, Erb finds only twenty-eight that are perfectly typical.

The only typical case so far reported in this country is that described by Dr. George W. Jacoby, of this city. The case reported here closely resembles a typical one, and is of an interesting character in many respects. Although the disorder is rare, it may be that when wider attention is called to it, other cases may be recognized by physicians in this country.

T. C.——, male, single, United States, aged thirty-five, merchant. The patient was referred to me by Dr. Clarence C. Rice.

Family history.—The family is a healthy one, with no history of nervous or tubercular disease, alcoholism, or syphilis, except that one sister suffers from some "spinal trouble."

Personal history.—The patient was delicate as a child, but had no special disease or nervous symptoms during his youth. He never indulged in sexual or alcoholic excess, and never had any venereal disease.

When fourteen years of age he had talipes varus in the left limb. Tenotomy was performed, and he wore an iron splint for a year or two, when the affection was cured, leaving this leg a little smaller in circumference than the right.

Present disease.—The first symptoms were noticed when he was about twenty years of age. They came on without apparent cause. He observed a stiffness in his hands, and difficulty in opening them after they were closed or when he grasped anything. The two extremities were affected about equally, the right slightly more than the left. He noticed that there was some stiffness in his legs when he began to walk. Later a stiffness developed in the muscles of mastication, so that he had to move his jaws for some time before he got them into good chewing order. He had to be a little careful, also, in swallowing. There was no muscular atrophy, but of late he finds that he tires very easily, especially in the arms.

He had, until a few years ago, a small larynx and a peculiar, high-pitched voice. After treatment for catarrhal troubles by Dr. Rice the voice became changed and normal in tone and pitch.

The sexual function seemed somewhat imperfect. His memory became a little impaired, and his power of concentration of thought lessened. Occasionally he seemed to lose entirely the meaning of remarks addressed to him, experiencing an attack of sudden absent-mindedness, but with no loss of consciousness.

The bladder, he thinks, is a little weak. He suffered from aching pains in the lower limbs.

Status presens.—The patient is a man slightly below medium size, intelligent in appearance, and with nothing abnormal noticeable in his general physiognomy, except a slight drooping of the lids.

Neuro-muscular.—He shows no ataxia in gait, or on standing no tremor or fibrillary twitchings.

Muscular development is good, but not remarkable.

---

[1] Paper read at a meeting of the New York Neurological Society, March 2, 1888.

except that his biceps and calf muscles are large and stand out conspicuously. Measurement around right relaxed biceps, ten inches; left biceps, ten inches. Muscular power in the arms is not in proportion to the apparent muscular development. Dynamometer, right hand, 40; left hand, 38 (normal, 45 to 50).

When he closes either hand, tonic contractions occur, and it requires a few seconds and some voluntary effort to open them. If the hand is tightly closed for several minutes, the spasm gradually relaxes and the hand can be opened readily. When the feet are forcibly and voluntarily extended, there is a slight tonic contraction in the calf muscles, but the phenomenon is but slightly marked. On examining the throat, tonic spasm of the pillars of the fauces was noticed by Dr. Rice. No other muscles of the body show this myotonic condition to tests. He describes it, however, as occurring in all the muscles of mastication and deglutition.

Mechanical irritability.—On striking the muscles of the arms, shoulders, and lower extremities, a welt of idiopathic muscular contraction always develops and remains for five to ten seconds. Striking the flexors or extensors of forearm causes a tonic contraction of the whole group. This is well shown on the extensors of the arm. With the elbow resting on the table, the extensors are struck with the percussion hammer; as a result, the hand is raised by a tonic contraction and then gradually falls. On striking the biceps a hard blow, not only is a welt produced, but a myoid tumor of brief duration also appears.

These myotonic phenomena are not observed in the trunk muscles or face.

The mechanical irritability of the nerves was not increased, but even seemed decreased.

Electrical reactions.—Electrical sensibility was, if anything, decreased to both currents.

Electrical irritability.—Faradic current: The muscular irritability was well marked, and perhaps increased. There was a decided after-contraction.

Nerve irritability was normal.

Galvanic current: With one pole on the back of the neck, and the other on the wrist or palm of the hand, and a current of ten to twenty milliampères, no wave-like contraction from anode to cathode, or *vice versa*, occurred (Erb's reaction). There was, however, an increased muscular electrical irritability shown; for tonic contractions occurred whenever the current was closed. These closure tonic contractions occurred with each pole, and lasted as long as the current passed. They were provoked by mild currents (5 to 10 milliampères). There was no opening contraction. The Ka CC was greater than An CC. The formula, therefore, was:

Ka CC > An CC.
Ka OC = O.
An OC = O.
Ka C Te.
An C Te.

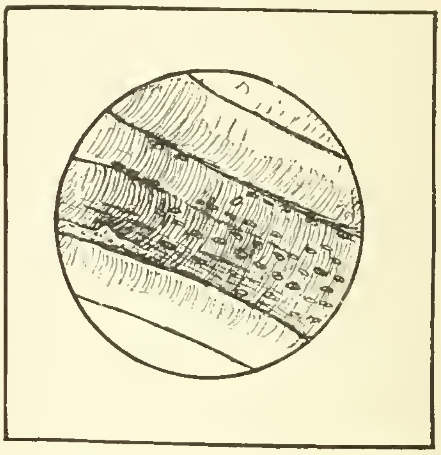
The faradic after-contraction and the closure tetanus occurring even with currents of 5 to 10 milliampères, were the most marked feature of the electrical reactions.

The phenomena occurred in the forearm and upper-arm muscles, and in the leg muscles, but not elsewhere. With one pole on the neck, and the other on the hand, the closure tetanus affected not only the flexors in the forearm, but, to a slight extent, the biceps—a kind of modified Erb's reaction.

Reflexes.—The patella tendon reflexes were lessened, but present. The triceps reflexes were normal. The skin reflexes were decreased.

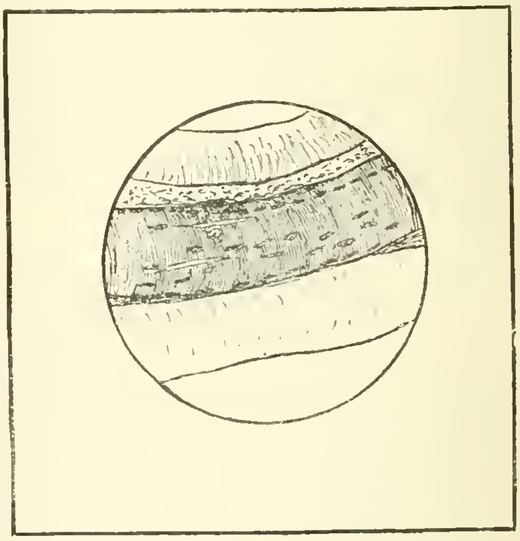
Organic Reflexes: The patient complained of some vesical weakness.

Sensations.—The patient seemed to have a slight bilateral ptosis. Vision was fair. I was informed by Drs. Roosa and Emerson, who had seen the patient, that last spring he suffered from a neuro-retinitis, and the eye still showed traces of it. Otherwise the fundus was normal. Smell and taste were, as the patient thought, dull, but tests showed nothing abnormal. Hearing was normal. General and cutaneous sensibility were normal. The patient showed a trace of muscular anæsthesia, as shown by tests for standing, walking, touching points on the body, but no loss of power to appreciate differences in weight. He described himself as having a tendency at times to festination, but he did not show it. Digestive functions good. Thoracic organs normal. Urine normal. There is apparent vaso-motor weakness. The hands are red; the feet and hands get cold easily. The patient complains bitterly at times of aching pains in the legs, particularly about the knees. His secretion of saliva is extremely profuse.



Microscopic examination of muscles.—I excised a piece of the right supinator longus, a muscle that showed myotonic reaction. I also harpooned a piece of this same muscle from my own arm. These specimens were hardened a little in alcohol and stained in picrocarmine and bismarck brown.

Dr. George W. Jacoby and Dr. Heitzmann were kind enough to examine the specimens and compare them with those from a typical case of Thomsen's disease described by the former gentleman. Their opinion seemed to be that the fibres presented some of the characteristic features of the muscle in myotonia congenita, viz., increase of muscle nuclei and a tendency to fissuring. I have studied them carefully, and compared them with normal fibres from the same muscle hardened and stained in a similar way. I present two somewhat crude drawings, which are accurate in their main features. It seems to me that there is an apparent increase of muscle nuclei, as indicated by counting a number of fields. Some fibres are quite large, but the average is not much above normal, being,



as measured by a stage micrometer, $\frac{1}{250}$ to $\frac{1}{350}$ of an inch in diameter. The fissuring is plainly present, both in torn and cut sections. While it may be mechanical, it is not present in the healthy nerve-fibres.

Conclusion.—The case here reported is certainly not a typical case, but it does present certain typical symptoms and typical electro-muscular reactions.

The history points to some central lesion of a hereditary degenerative character. In some respects the patient suggests a case of pseudo-hypertrophic paralysis, and in others hereditary ataxia.

Such a case is, I venture to think, highly instructive, as showing the kinship of the true myotonia congenita to other primary degenerative disorders.

It is hoped that the publication of the case may lead to the observation of others by American physicians, and that more light may thus be thrown upon a most curious and obscure malady.

The literature of this subject, since the publication of Erb's monograph in 1886, is as follows:

T. Buzzard: *Lancet*, vol. i., 1887, p. 972.

George W. Jacoby: *Journal of Nervous and Mental Diseases*, March, 1887.

M. Bernardt: *Centralblatt f. Nervenheilkunde*, November, 1887.

Besides Erb's work, which is in German, the literature of the subject was collected by Dr. P. Chapman, in *Brain*, April, 1883, and again by Dr. Hale White, in *Brain*, April, 1886.

THE CUMULATIVE ACTION OF THE GALVANIC CURRENT.[1]

By A. D. ROCKWELL, M.D.,

PROFESSOR OF ELECTRO-THERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, N. Y.

I USE the term cumulative to express the increased efficiency of the galvanic current when it is applied along the course of a nerve without interruption. It occurred to me that the term storage might be suitable, for it is evident that when the galvanic current passes continuously for a long time its strength increases in a marked degree. Energy is undoubtedly stored, perhaps in the same sense, but certainly not in the same demonstrable way that chemical action is stored in the ordinary storage-batteries. By this method a secondary current is always at command, and can at will be transformed into heat movement or chemical action. In the continuous action of the galvanic current on living tissue we do, indeed, get heightened energy, but hardly an actual storage of chemical action, for it cannot be gathered and transmuted into other manifestations of force.

The phenomenon of the increased efficiency of the continuous action of the current, both in deflecting the needle of the galvanometer and in overcoming conditions of disease, is apparent; but, as it cannot be ascribed to an actual storage, a satisfactory explanation is still wanting, and the term cumulative may perhaps express better than any other its real meaning and significance. One factor that goes to make up this increase, as is well known, is the better conductibility of the tissues gradually taking place at the seat of the recomposition of the current, a result due to congestion of the skin and adjacent parts under the electrodes.

That this explanation, however, of the increasing strength of the current when continuously passed through living tissue is but partial, can be readily demonstrated. I apply the current from a given number of elements to the arm and forearm, and seven milliampères are immediately registered.

In two minutes there is an increase of one degree, in two minutes more an additional degree, and in eight minutes twelve milliampères are registered. That this extraordinary increase of strength is not caused by improved conduction *simply*, I soon satisfy myself, by applying vigorous friction to the other arm, and, when the congestion is as intense as that produced by the electricity, the electrodes are applied. Instead of seven the instrument does, indeed, immediately register ten milliampères, but it is not until four minutes more have elapsed that the additional two degrees are registered. Another phenomenon, even more interesting than this, is the increased strength observed upon a reversal of the direction of the current. A current from fifteen cells was applied to the thigh of a patient (small electrodes being used), and the poles kept in position until twelve milliampères were registered. The current was then suddenly reversed, when the milliampèremeter immediately registered fourteen. To analyze the molecular disturbances that evidently take place during the passage of the galvanic current is a labor of the greatest difficulty, and the phenomenon is one not yet thoroughly understood. Evidences, however, of the chemical action of electricity as it passes through the tissues are not wanting, and this sudden increase of strength is undoubtedly due to the electrolytic or polarizing action of the current, exciting a secondary current in the living body similar to what is observed in a reservoir or secondary pile.

In contrast to this thoroughly scientific and demonstrable doctrine of Matteuci, we have the more vague and confused teachings based on the theory of electrotonos, the laws of which, while of great value, do not by any means account for all the phenomena and therapeutical activities of the galvanic current. On the other hand, the statement "that a therapeutical system, built on the opposite anelectrotonic and katelectrotonic effects rests upon an imaginary basis," [1] seems to me altogether too sweeping.

To intelligently appreciate the force of those barbarous terms, anelectrotonos and catelectrotonos, we must keep in mind the purely physical effects of the current in the tissues. These effects are exceedingly complex, for the composition of all organic tissue is complexity itself. Combinations and decompositions take place which are yet of an entirely unknown character.

The analogue of the electrolysis of organized tissue—animal or vegetable—although less complex in its nature, is seen in the electrolysis of acidulated water.

Acids go to the positive and alkalies to the negative pole; now it is a fact of physiology that acids diminish the irritability of nerves, while alkalies increase it. Anelectrotonos and catelectrotonos may therefore be caused by acids at the positive, and alkalies at the negative pole. However this may be, it is as true now as when first demonstrated by Pflüger, that a nerve is *excited* by the appearance of catelectrotonos and the disappearance of anelectrotonos, but not by the appearance of anelectrotonos and the disappearance of catelectrotonos. In other words, irritability is increased near the negative pole, this condition of catelectrotonos increasing as the current runs up to a certain point.

On breaking the current the negative modification, or condition of diminished irritability, appears for a moment and then disappears. Near the positive pole, on the other hand, the irritability is diminished after closing the current. On breaking the current there is an increase of irritability or positive modification, which appears to be greater when the current has been allowed to run a lông time. But whatever theory we accept, the fact remains that it is not alone the increased conductibility of the tissues that enables the current to act with such increased vigor, but phenomena of a purely physiological or physico-chemical order. It is in the consideration of paralysis in its various forms, more especially, that these cumulative effects of electricity would seem to be of value, but experience points to other conditions where it is applicable. In paralysis of central origin, where there is increased irritability of the paralyzed nerve, any attempt to produce muscular contractions is uncalled for and may do harm. The continuous passage of a galvanic current, however, is useful and, provided no interruptions are allowed and the current is not reversed, a moderate modification of the excessive irritability may be quite confidently expected.

---

[1] Read before the Section on Practice, New York Academy of Medicine, February 21, 1888.

[1] Conditions of the Unipolar Stimulation, etc. Brain, Part IX.

In cases of hemiplegia, where the irritability of the nerve is more or less impaired, the continuous passage of the current accomplishes more for the patient than the attempts at frequent muscular contractions that are so popular. The difference in the treatment of hemiplegia with increased nerve-irritability and hemiplegia with decreased nerve-irritability is simply this: In the former it would be as inadmissible to allow interruptions of the current, or a change in its direction, as it would be in a case of neuralgia.

In the latter, on the contrary, a few interruptions can, with good effect, be given at the close of an uninterrupted seance, and a reversal of the current adds to the efficacy of the treatment. My attention was called to the practical value of what I term the cumulative effects of electricity by observations more particularly in various forms of peripheral paralysis and in the essential paralysis of childhood. I have, of course, treated many cases of infantile paralysis, and, in common with others, have had both successes and failures, and up to within a few years all of these results, both good and indifferent, followed the rough and excessively stimulating method of current-interruptions. Before electricity had the slightest recognition as a constitutional tonic and sedative, and as such indicated in a wide variety of disorders, it was rather contemptuously assigned the position of a harsh stimulus, and of some value in "pricking up paralyzed muscles."

No statement of the damage inflicted by the practical application of this crude and primitive enunciation has ever been made, but I am confident that great and fatal mistakes have arisen therefrom.

Two cases of infantile paralysis have come under my observation where but the slightest suggestion of nerve-irritability existed, and when, after rough usage—in one instance by the faradic and in the other by the galvanic current—the slightest vestige of vitality in the paralyzed members became extinguished, and the cases hopeless. On the other hand, I have seen cases where the nerve-irritability was equally impaired pursue an entirely different course, under an entirely different method of treatment. Sudden galvanic shocks, whatever useful purpose they may occasionally serve, are often dangerous in the extreme. Their effects are, in the main, undue stimulation; and, in their relation to nutrition, destructive rather than reconstructive.

The continuous passage of the current, however, while in a certain sense stimulating in its effects, combines influences that are sedative and tonic, and pre-eminently reconstructive, and is alone equal to the task of resisting progressive degenerative changes in nerve and muscle. I could easily cite a number of cases of infantile paralysis as illustrative of the principles here enunciated, but, not to consume too much valuable time in this way, I will crave your indulgence only while I give, with some minuteness of detail, the history of a single case. It was in the observation of this case more especially that I became thoroughly alive, on the one hand, to the importance of the continuous action of the galvanic current, and, on the other, quite as positive as to irreparable damage to nutrition, in conditions both of increased and diminished nerve-irritability, by the injudicious use of the interrupted galvanic current.

In October, 1884, a little boy, aged five, was brought to my office suffering from complete paralysis of the right leg, and, in a less degree, of the left also. The muscles of the right thigh and leg had atrophied to such an extent that the bones seemed to be covered with little more than skin, and it is hardly necessary to say that to the faradic current there was not the slightest reaction. The galvanic current also seemed at first unable to elicit any evidence of nerve-irritability, but upon more careful electrical interrogation exceedingly slight contractions of some of the extensors of the foot were observed, but associated with decided qualitative changes.

In the left leg, which had atrophied to a considerable extent, I found quantitative changes, but no reaction indicating tissue-degeneration. About a year before, the child had been seriously reduced in flesh and strength by a prolonged diarrhœal attack, culminating in a series of severe convulsions, followed by fever and associated, probably, with acute polio-myelitis anterior. Paralysis of the legs followed, and for a few days the loss of voluntary motion was complete. Within a week, however, without special treatment the limbs gradually began to resume their function, until the patient could freely move them, the left one becoming sufficiently strong for him to bear his weight upon it.

Improvement seemed to stop at this point, and some time after the mother, although not a poor woman, sought advice at one of our college clinics. Here electricity was used, and, according to the statement of the mother, the foot became rapidly extended many times in rapid succession during the application. This process, evidently a strong interrupted galvanic current, was repeated quite a number of times at varying intervals, until finally the observant mother noticed that not only were the contractions less marked but the power of voluntary movement in both limbs was decreasing in a decided degree. She ceased her visits, abandoning all treatment; but the limbs steadily continued to decrease in strength and size until, when I saw the child, the left leg had, as already stated, reached an extreme condition of atrophy, with marked reaction of degeneration in the few muscles that still retained some slight evidences of electro-muscular contractility. The case seemed sufficiently hopeless, but, explaining to the mother, who dreaded any further trial of electricity, the entirely different method that would be adopted, and impressing on her mind the necessity of patience, I began the application of the uninterrupted galvanic current with a strength of only five milliampères, and a seance of five minutes in duration. The applications were for a time made daily, and at each sitting the duration was increased by one minute and the strength of the current by one milliampère, until, at the end of two weeks, the patient was receiving applications of fifteen minutes and a current-strength of fifteen milliampères.

During this time, although reversed currents were used every day, not a single galvanic interruption had occurred. Examining, now, the condition of electrical excitability, I was gratified to find not only increased vigor in the contractions of the extensor muscles, but slight yet appreciable contractions in muscles which had before failed to respond to the most searching electrical interrogation. The reactions were yet, however, those of degeneration. This patient continued under observation and treatment a long time, the limbs improving from month to month in nutrition, and necessarily in electrical reaction. At the end of eight months the patient could walk aided by a cane, although with considerable awkwardness, and the electrical reactions were normal with the exception of a slight quantitative defect in the left leg, which continued also quite deficient in size. The lessons to be learned from this case are undeniably important.

If the mother could be trusted in her statements, and she was an unusually intelligent and observant woman, the main points were these:

Following an attack of acute polio-myelitis anterior we have the characteristic paralysis of the lower limbs.

Spontaneous improvement, but only up to a certain point, soon appears. Shortly after, strong interrupted galvanic currents are most imprudently administered, resulting finally in almost entirely obliterating a condition of nerve-irritability that was already greatly impaired. The damage inflicted was almost irreparable. The muscles waste and the reaction of degeneration appears.

Finally, when the paralysis was practically complete, the aid of a mild continuous galvanic current was evoked, increased from time to time as prudence dictated. Nutrition is immediately and favorably influenced—the muscles increasing in size and strength, the electrical reactions becoming normal and, in the end, the disabled members are sufficiently restored to be of decided service. In various other forms of disease these principles are no less applicable than in paralysis, the difference being that, while in neuralgias and most nervous symptoms it is more universally understood that continuous currents are indicated, in paralysis it is too often taken for granted that the more prompt and vigorous the stimulation the greater the benefit.

The injury that may be inflicted upon paralyzed members by this method has already been emphasized, but it is to be observed that such injury does not as a rule follow occasional or accidental shocks, but only when administered with a good degree of vigor and as a supposed necessity of treatment.

In neuralgias, however, in the many forms of nervous disease characterized by excessive irritability, as chorea, epilepsy, hysteria, and even in exophthalmic goitre, interruptions of the current, although only accidental and occasional, may be followed by increased pain, by an aggravation of choreic symptoms, by an instantaneous epileptic attack, by severe hysteria, and, in exophthalmic goitre, by increased rapidity of the heart's action.

In all of these conditions we desire, not stimulation but sedation, and therefore interruptions of the current, or even large and rapid variations in its density, are to be avoided. Slow and slight variations in density, provided the current remains closed, I have not found to produce unpleasant stimulating effects.

One more practical observation. Exophthalmic goitre is a disease that can be treated with far greater success than is generally believed. I have myself reported fifteen cases, of which nine were either greatly benefited or approximately cured.[1] It is hardly necessary to say to anyone cognizant of the peculiar characteristics of the disease that uninterrupted and unvarying currents are called for. There are, however, exceptions to this rule. Certain cases seem to demand a stronger impression than can be produced by a constantly flowing galvanic current—if not at first, yet further along in the treatment. They would act badly under interrupted currents, but, by rapid and large variations in the closed circuit, a modified stimulation is obtained which in my own experience has proven of invaluable service in several difficult cases.

---

[1] New York Neurological Society, April 7, 1885.

Women in Former Times.—Up to the fourteenth or fifteenth century women spent most of their time alone, and seldom went abroad. Francis I. was the first who allowed them to come to court. In the thirteenth and fourteenth centuries elegance had scarcely any existence, and even cleanliness was considered somewhat dangerous to health. The use of linen was not known, and even the most delicate of the fair sex wore woollen chemises. They had meat only three times a week. Wine was only to be had at the apothecaries, where it was sold as a cordial. And to ride in a two-wheeled cart along the dirty rugged street was considered so grand that Philip the Fair forbid all but the wives of the nobles to indulge in it. In the times of Henry VIII. the peers of England carried their wives on horseback behind them, to and from London and their country-seats, wrapped in mantles of cloth, with hoods of waxed linen to protect them from cold and wet.

Head-dresses.—Thomas Conecte, a Carmelite monk, was burnt at the stake in 1434. His principal offence was his vehement sermons against the enormous head-dresses of the period. They were so high and broad, with two flaps on each side, of such unaccountable size that it was impossible for a fashionable woman to pass through a door, except sideways.

MUSCULAR INSUFFICIENCY.

By RICHARD H. DERBY, M.D.,

SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

Strabismus, in its broadest sense, is a deviation of a visual axis, more strictly a concomitant deviation of a visual axis. This associated concomitant deviation of the one axis when the other is fixed is measured by a certain angle, and this angle remains always the same. The actual movement in concomitant squint is not diminished, for if the excursion made by the eye inward is relatively with that of the other eye smaller, the excursion outward is relatively greater; in other words, here "the arc of movement is simply turned in the direction of the affected muscle."[1]

Now, in close connection with what has been said concerning absolute strabismus is the question of dynamical strabismus, or muscular insufficiency.

Dynamical strabismus is that condition where the visual axis deviates, not when both eyes are open and the power to blend double images is present, but when one eye is closed. Binocular or stereoscopic vision is maintained but with an effort. In health the eyes, with the muscles that move them, are in a condition of balance; for near objects the visual axes are converged without effort, while for distant objects the parallelism of the axes is maintained. For all distances, in the normal condition, the muscles which move the eyes in a vertical plane act together and maintain vertical equilibrium. When this normal condition of equilibrium in either the horizontal or the vertical plane is disturbed, we have what has long been known as dynamical strabismus, or muscular insufficiency. Whether it be that the internal or external recti are weak, or one of the muscles concerned in moving the eye upward or downward is deficient in power, the complex of symptoms is, in the main, the same, and we may now with advantage study them.

Such a patient complains that his eyes become soon fatigued; in the evening especially, he cannot read or write for any length of time, for after a while the letters grow uncertain before his eyes; he can work but for a few minutes by reason of the pain which centres in his eyes and head. He can read for a page or so, and then the print becomes indistinct, blurred. He does not see the printed words as readily as before; he "does not catch on." For middle distances the trouble asserts itself; often he cannot look at a person close at hand without shutting one eye. Even in the act of fencing or sparring, the patient must occasionally stop and "fix" his eyes. He rests himself in reading by closing one eye. The last enumerated symptom is perhaps of all the most suggestive, and if the further statement is made that objects sometimes appear double to him, our attention is inevitably turned to the muscular system of the eyes. There is no evidence of strabismus; but let your patient now look at an object with one eye, and holding your hand as a screen before the other, watch its behavior while fixation is demanded of the first. While the first fixes, the covered eye turns slightly in; uncover it and he makes a movement outward to fix the object. The same thing occurs whichever eye is covered, and our diagnosis is at least in part established, and our patient has probably weak external recti. Again applying this same simple test in another case, the patient looks at an object with one eye, and you will see that the covered eye turns slightly out; uncover it and he makes a movement inward to fix the object. Here, then, is probably a case of insufficiency of the interni. The frequency of the latter affection is what we might expect when we reflect that there are few muscles more constantly called into play than the interni. Every object to be seen close at hand requires the convergence of the two eyes, that is, a greater or less contraction of these two muscles; the nearer the object is brought, the greater the work.

---

[1] Von Graefe: Clinical Lectures.

Hence the weakness of these muscles shows itself especially in reading.

Another test, to be applied in the suspected case of muscular insufficiency, consists in placing before one eye a red glass, and directing the patient to fix with both eyes a candle-flame held at varying distances before him. Often, if insufficiency of the recti muscles of any considerable degree be present, he will instantly say that he sees a red light and a white one, either side by side or one above the other, according as a lateral- or vertical-working muscle is deficient in power; and that the two images are seen to fuse together as soon as the red glass is removed. The explanation of this is, that the capacity for fusion of the images seen by each eye being reduced, the colored glass reduces the instigation toward binocular single vision. This is one of the surest tests we have for muscular insufficiency.

We must not, however, be content with merely ascertaining the deviation of the eyes under the covering hand, or by weakening the natural disposition to binocular sight by the use of a colored glass, or by advancing an object toward the eyes until the weaker eye deviates; we must determine more carefully the degree of the affection. To this end we make use of the tests with which Von Graefe also supplied us more than twenty years ago. Later investigation has failed to give us any more accurate tests than that afforded by the use of the prism in inducing artificial diplopia. In the first place we examine the dynamical condition of the internal and external recti. To accomplish this we place a prism of more than ten degrees, with its base downward, before one of the patient's eyes. Ordinarily, by thus superimposing images their fusion is rendered impossible; so, when the patient abandons his eyes to the action of the lateral-working muscles there occurs homonymous or crossed diplopia, according as there is insufficiency of the external or internal recti. With such a prism thus held we examine the condition of the eyes, first for the distance and then for the reading distance. For the first it is convenient to use a candle-flame; for the second a black dot with a vertical straight line, or a dot without the line, or a short oblique black stroke placed on the centre of a sheet of paper. According to the distance at which the test-object is held, the patient will see two candle-flames or two dots, but not on the same vertical line. The right eye may see one of them to the left, and the left eye one of them to the right. This is crossed diplopia, and corresponds, as we know, to divergence of the eyes, or the diplopia may be homonymous, and this points, of course, to convergence of the eyes. Whichever the condition may be, we must now look for the prism, which, held vertically with its base in or its base out, brings the images on the one vertical line. The degree of the insufficiency is determined by the strength of this prism necessary to thus superimpose the images. Having thus measured the degree of the insufficiency, our examination is not complete. We must now ascertain the power of the internal and external recti in the interest of binocular vision; in other words, we must ascertain what degree of prism can, with its base in and with its base out, be overcome without provoking double sight. This is known as a measure of the power of abduction and of adduction. This, as we shall see later on, is a matter of the greatest importance where any operative procedure is deemed necessary for the relief of the dynamical difficulty.

Muscular asthenopia, as has been long well known, may also be due to an insufficiency of one of the muscles concerned in moving the eye upward or downward. Tests similar to those in use for a detection of dynamical divergence and convergence are here employed, except that here, of course, in our examination with the prism, lateral diplopia is first induced. Such a prism as cannot be overcome by abduction is placed before one eye, its base directed exactly inward; the patient is now asked to estimate the difference in height of the two images. If the image seen by the right eye appears higher than that seen by the left, we note that the right must stand lower, and that there is insufficiency of the right superior rectus.

The following cases, taken at random from my case-book, will illustrate the varieties of muscular asthenopia which we have been considering. The first is a case of insufficiency of the interni.

W. P——, aged sixteen, from San Francisco, came to me November 19, 1883; is a nervous, pale boy, who has left his school on account of asthenopic symptoms. He often rests himself in reading by closing one eye. Upon looking a person intently in the face he has to "stop and fix his eyes." Patient can, at will, produce diplopia. The images stand side by side, and are of equal height. Each eye is emmetropic, and vision is 1.

In the reading distance there is insufficiency of the interni of 12°; in 3M. this insufficiency amounts to 6°. Patient was told to wear prisms of 5° (bases in) before each eye, and the faradic current was used locally. On December 5th, had been wearing these prisms for several days; he reported that he no longer had double vision. This day, under ether, a careful tenotomy of the right external rectus was made. Directly after the operation there was 2° of divergence in the position of election (the light held 15° toward the side of the unoperated eye). On December 7th patient was no longer able to induce diplopia on the middle line. Later in the month he went to his home, greatly relieved of his asthenopic symptoms.

The next case is one of insufficiency of the externi.

Miss C——, aged twenty-one, came to me October 22, 1885. She complained that she could not see the print as readily as formerly. "I do not catch on." For a distance of 5M. there was insufficiency of the externi of 4°, but at the reading distance insufficiency could not be demonstrated by the ordinary tests. At 5M. adduction was 35°; abduction, 5°. There was H.25D. of each eye, and absolutely normal vision. The ophthalmoscope showed a total H. of at least 1D. Patient received a reading glass, o.u. +.75D., combined with prisms 2° (bases out).

December 1st, patient reported that she could read a page with ease, but that then the print became indistinct. Exercise with the stereoscope daily was enjoined.

January 4, 1886. Patient states that for distant vision she had no trouble, but that she could not look at a person close at hand without shutting one eye.

April 29, 1886. Under cocaine, a tenotomy of the right internal rectus was made, a small horizontal incision over the insertion of the muscle being made in the conjunctiva. Immediately after the operation in 3M. on the middle line there was dynamical divergence of 2°. To reduce the effect of the operation a suture, including four lines of the conjunctiva, was applied over the insertion of the divided muscle.

April 30th. In the position of election there is dynamical convergence of 3°–4°. The suture was removed, and the patient directed to wear her abduction glasses.

May 5th. Patient can wear o.u. prisms 7° (bases in) with comfort. In 4M. abduction is 19°; adduction, 45°; in reading distance abduction, 17°; adduction, 45°+.

May 15th. Patient now no longer finds the page grow gray in reading; can read for half an hour with ease, and can look a person steadily in the face.

The following two cases are of insufficiency of a superior rectus muscle; in the one case associated with weak interni, and in the other with weak externi.

Mrs. F. M—— is an artist; came to me November 25, 1872. Seven years before, while modelling a medallion, she was compelled to work much at night. She could not well see to do her work. Application caused pain about and back of her eyes. She could work one day and "the work would look all right, and the next day everything seemed crooked." In both eyes H. $\frac{1}{42}$ and

V. of each $\frac{20}{XX}$. In 15′ dynamical divergence of 2°, and so increasing up to 10″. Punctum proximum good. With a strong prism of adduction that could not be overcome, the right eye stood higher by 2°.

The second case, Mrs. W——, came to me first, June 3, 1875. Patient had always been near-sighted, and latterly the myopia had increased. The eyes examined separately showed M. $\frac{1}{5\frac{1}{2}}$, V.$=\frac{20}{XL}$. Patient complained of discomfort in reading by lamplight. In 3′ the red glass held before one eye produced homonymous diplopia, the left eye standing higher, binocular vision is ordinarily without difficulty maintained. Patient received for reading the following glasses: O. d. −4D.; o. s. −4D., combined with prism 3° (base down).

The next case to which I would refer is one of marked insufficiency of the right superior rectus.

Miss B——, aged twenty-seven, came to me June 27, 1873. Patient complained of frequent diplopia and marked asthenopic symptoms. On each eye E. and vision 1. The ordinary tests for reading distance revealed an insufficiency of the externi of 4°, and a variable amount of insufficiency of the right superior rectus, amounting at times to 9°. Patient was directed to use a prism of this degree before the right eye, with a view to developing the full amount of the vertical insufficiency. On January 1, 1874, with a prism of 12° (base up) in front of right eye, the measure of the insufficiency was found. Then the light being held at 10′ and 35° below the horizontal plane, the images remained for a time on the same level, and there was occasionally slight convergence, and at times slight divergence. On February 2d she could wear for a time, in the interest of single vision, a prism of 15° (base up) in front of the right eye.

May 3, 1874. A partial tenotomy of the left superior rectus was made, leaving $\frac{3}{4}'''$ of the innermost fibres still undivided; a suture seizing 2‴ of conjunctiva, closing the wound, was applied. Directly after the operation, the candle-flame, held 10′ away and 15° below the horizontal plane, the left eye stood lower 1°–2°. On the evening of May 6th the suture was removed. May 20th, at 10′ with prism 16° (base in) before right eye, the left eye stood higher by 1°. On May 22d there was in position of election dynamical equilibrium.

From the cases which have here been considered, briefly detailed as they have been, it is evident that in the treatment of muscular asthenopia we have, both in the use of prisms and in a tenotomy, an efficient means of relieving the ocular affection. We have seen that this class of cases differs essentially from real strabismus; the trouble is dynamical, and whether the muscle at fault is the rectus, internus, externus, superior, or inferior, the affection in each and every case is a limitation of the capacity for fusion in the interest of comfortable binocular vision. In another paper we have considered the influence of dynamical strabismus as an active factor in causing progressive myopia. Before leaving, however, this interesting subject a single word should, with justice to the illustrious Von Graefe, be said of the great service which he rendered to this hitherto but little understood chapter of ophthalmic medicine. As I said before, all the tests employed for the detection of these anomalies of the ocular muscles were introduced by him. I know of no better or more exhaustive work on this subject than that of Von Graefe, "On the Operation for Dynamical Divergent Squint," contained in *Zehender's klin. Monatsblätter* for August and September, 1869. If the reader has mastered the principles there so lucidly and so exhaustively laid down, this class of cases will present few difficulties to him. Under the names of exophoria, esophoria, and hyperphoria of recent writers, we find the affections described which we have been considering. It is a matter open to discussion whether the new names are better than the old, but this much is sure, that in every case of asthenopia the dynamical condition of the muscles of the eyes should receive our most careful attention.

Clinical Department.

TWO UNUSUAL AND FATAL CASES OF ABDOMINAL INJURY.

By M. SINGER, M.D.,

GALVESTON, TEX.

JAMES C——, twenty-seven years of age, was admitted to St. Mary's Infirmary, Galveston, on March 9, 1886, complaining of pain in the hypogastrium and inability to void his urine.

He stated that on the preceding night, while partially intoxicated, he had picked a quarrel with someone, and had received a blow on the eye and a kick in the abdomen. This occurred about midnight, yet he stayed out and kept on drinking until 2 A.M., when he returned to his boarding-house and went to bed. He sought admittance to the hospital on the same morning, at about 10 A.M., and said that he had not passed water since the previous night, although he had made frequent efforts to do so. When a catheter was passed, spasm of the neck of the bladder had to be overcome; then about a quart of bloody urine was evacuated. The patient had never had a stricture. At this first examination no external mark of violence was seen on the abdominal surface, and the pulse was full and strong and normal in beat. The history of the case and the presence of blood in the urine led us to suspect rupture of the bladder, yet, owing to the time that had elapsed since the occurrence of the accident (ten hours), and the medico-legal aspect of the case, the surgeon in charge of the wards did not deem it prudent to operate. At this time the patient was not suffering from shock; soon, however, unmistakable signs of peritonitis made their appearance. Catheterization was resorted to at regular and frequent intervals, and at one time as much as three quarts of bloody urine was drawn off. Despite the suffering caused by the peritoneal inflammation, the man preferred sitting up in his chair, or walking about in a "doubled up" manner, to remaining quiet in bed, and no amount of persuasion could keep him still. Collapse set in in due time, and death took place sixty-four hours after the receipt of the injury.

At the post-mortem examination, made eighteen hours after death, no sign of external injury, save an ecchymosis of the eye, was seen on the body, which was muscular and well developed. When the abdominal cavity was opened the intestines presented, offering the usual signs of well-established general peritonitis. The bladder was semi-collapsed, and in it, at its superior and posterior part, there was a rent three inches in length, extending in an antero-posterior direction. This tear established a free communication between the interior of the bladder and the peritoneal cavity. The recto vesical cul-de-sac below the rupture contained fluid similar in appearance to the urine obtained by catheterization from the man during life. The walls of the bladder were found normal, and the urethral canal showed no evidence of stricture.

The principal points of interest in this case are the non-evidence of any outward sign of violence, not even the slightest discoloration of the skin being apparent, and the complete absence of shock.

The following case illustrates by what terrible consequences an apparently trifling external injury may be followed:

John M——, thirty-six years of age, was admitted to St. Mary's Infirmary on May 25, 1886, at 2 A.M. He was then in a state of collapse, and could but imperfectly answer the questions propounded to him. All I could learn from him was that he was a railroad laborer, and on the preceding day had been occupied in discharging lumber from a car. While the train was moving at the rate of about seven miles an hour, the man was pushing the planks off the car in front of him. One of these planks touched the ground on its foremost end, while the other extremity, still raised in the air, struck him a severe blow in the lower part of the abdomen. By this accident, which took place one hundred and fifty miles from Galveston, the man was at once put in a helpless condition, and therefore was sent to the company's hospital in this city, without having received any medical attention meanwhile. On physical examination a dark ecchymotic spot was seen in the left inguinal space, at about an inch above the middle of Poupart's ligament. The abdominal muscles were firmly contracted, and the man complained of severe pain in the suprapubic and umbilical regions. After several attempts I succeeded at last in passing a catheter into his bladder, and withdrew some smoky-looking urine, which was found, on microscopical examination, to contain some blood-corpuscles. This led me to suspect rupture of the bladder. Prompt treatment directed to the relief of the collapse proved to be without avail, for the man died at 1 P.M. that day, twenty-three hours after the receipt of his injury.

At the post-mortem examination, held four hours after death, a great deal of fetid gas escaped as soon as the peritoneal cavity was opened. This aroused my suspicion as to possible rupture of the bowel, and I began at once a careful examination of the gut. In spite of the short period that had elapsed since the receipt of the injury, I could already detect well-marked signs of a general peritonitis, for an exudate of lymph had begun to unite the several coils of intestine. During the inspection a yellow, turbid fluid, having a distinct fecal odor, escaped from the abdominal cavity. A solution in the continuity of the gut was discovered at about the junction of the jejunum with the ileum. At this place it seemed as if the intestine had been cut through by some sharp instrument, and the two divided parts had become adherent to one another by the inflammatory exudate, which bound them side to side, giving them a resemblance to the two barrels of a shot-gun. A careful examination of the remainder of the small intestine and of the large one failed to disclose any other lesion, and there were no signs of injury of the kidneys or bladder. The spot on the integument where the blow had been received was also carefully investigated, and the lesion found to be only skin deep, without perforation even of the abdominal muscles. The patient, it should be added, was lean-bellied and sparsely built, and there is no doubt that the blow upon the gut, as the latter lay against the promontory of the sacrum, caused the intestine to break.

EIGHTY-ONE DAYS WITHOUT A NATURAL MOVEMENT FROM THE BOWELS—STRICTURE OF THE RECTUM.

By F. W. EDWARDS, M.D.,

WILMOT FLAT, N. H.

JANUARY 20, 1888, Susan B——, unmarried, nearly fifty years of age, came to my office to consult me, as she "was slightly constipated and could eat but little as it hurt her stomach." The history she gave me then was as follows: She had never enjoyed perfect health, but was always delicate, and had probably injured her health at her trade of dressmaking. Her bowels had always been regular and acted in the morning, the fæces coming away with a rush as though she had taken a cathartic, and she was able to restrain the movement for only a few seconds. She had for some years previously been troubled a little with a sore feeling at about the middle of the transverse colon. This looseness of the bowels continued until the first of last May, when her menopause began, and since then she has been very constipated, going, at times, ten days without an evacuation of the bowels. I gave her some mild cathartic, and recommended maltine with pepsin and pancreatin, as she told me at this visit she was only a little constipated. She began taking the maltine January 23d, and I did not hear from her again until February 4th, when she came to my office and said the medicine had done her no good. I asked her how long it was since her bowels had moved, when she replied "not very long." I then gave her aloin, one grain, and compound cathartic pills, two of each a day. February 7th, I was called to her, and found her suffering but little, but she had vomited quite freely the night before. She then told me that her bowels had not moved since two weeks before her first visit to me, and two weeks prior to that she had had but one small ball of fæces pass. In fact, from December 20, 1887, to February 4, 1888, a period of forty-nine days, her efforts at defecation had amounted to *nil!* The lady is of a retiring disposition, and did not wish me "to think her complaining." I began at once active catharsis, although I suspected a mechanical obstruction of the bowels. As I could get nothing to pass, I called a brother-physician in consultation. We continued the cathartics, adding croton-oil, etc., and I tried to force sufficient water into the rectum to overcome the obstruction, but to no avail. Of course, I added everything to the water (hot and cold) that could be thought of and obtained. I could get but three gills, at most, into the rectum, and when I tried to pass a rectal tube (one-half inch) up to the point of obstruction my efforts were in vain. My diagnosis was "stoppage of colon at the middle of transverse portion," but, when all my efforts could not make the tube pass the flexure, I felt almost certain that the obstruction was lower down than where I had placed it before. On February 15th I aspirated the bowels in two places, and gave exit to a quantity of sulphuretted hydrogen, but it did not reduce the bloated and tympanitic bowels to any extent. One symptom, or the absence of it, rather, surprised me, and that was *vomiting!* The patient vomited but twice after the first day I was called, and but very little came up at either attempt, although she strained and gagged for three or four hours each time. On February 22d I sent for Dr. C. P. Frost, of Hanover, and when he had examined the patient he concurred in the diagnosis, and, as she was now very weak, we decided to let her take her own choice as to whether she wanted an operation or not, and, after the condition of affairs was stated to her, she decided not to have an operation as she had but one chance in a hundred. Two days later she began to pick up and got quite strong, but her abdomen was very much bloated and the skin stretched so tight I could hardly get a fold of it up to give her a hypodermatic injection of morphia. I gave her two injections daily, and sometimes a third. At first I gave one-sixth of a grain, but was obliged to increase the dose to three-fourths of a grain each time. February 28th, she had quite a little movement from her bowels, and, two hours or so later, another smaller one. Both very loose, and each contained mucus and pus. Patient was highly elated and said she was going to get right up, but I was afraid her bowels had ulcerated and given way, so I told her family not to rejoice, and gave them my reasons for expecting death at any time. From this she gradually lost strength and sank away until, March 10th—eighty-one days from her last natural defecation—she calmly died.

Autopsy, twenty-nine hours after death. The abdomen was greatly distended and purple, the abdominal walls very thin, and the subject was terribly emaciated. After letting off gas, I found quite a little adhesion and inflammation at the cæcum and vermiform appendix, also at the gall-bladder and ductus communis choledochus, where the membranes were so thin and weak they would tear with handling. Every inch of the bowels seemed full and contained fæces. The cause of all the trouble was a cartilaginous band, about one and a half or two inches wide, which had gradually occluded the gut completely from seven and a half to nine inches above the anus. Below the band the channel was narrowed and filled with very thick pus, and at the upper part of the band it was ulcerated through, and there was a small opening the size of a lead pencil into the gut above, but it required some considerable force to get the finger through to the anus, after cutting the band off, on account of the small channel and the thick pus.

The liver was very much diseased, and it was a matter of astonishment why the patient did not suffer more from hepatic troubles and symptoms. Was this band malignant? There is scrofula in the family and some cancer, but I could not get a piece of band to examine with the microscope. Drs. Weymouth, Goodhue, and George Weymouth were present at the post-mortem, and my thanks are due to Dr. Goodhue for kindly assisting me at same.

CONGENITAL BALDNESS.

Dr. F. Semeleder, of Mexico, reports the following: "A girl of twelve years was brought to me; when she was born she had only a few long hairs; soon they fell out, and no hair has ever since grown on her head. The head has not the shiny appearance of that of a bald man, but the skin is dry and looks like shagreen-leather. The girl has no other deformity. She has brothers and sisters, none of whom is bald, nor are her parents."

Progress of Medical Science.

Intraperitoneal Rupture of the Bladder.—At a recent meeting of the Royal Medical and Chirurgical Society (*The Lancet*) Mr. W. J. Walsham brought forward a case of intraperitoneal rupture of the bladder, in which abdominal section was performed and the viscus sutured. The patient, C. H——, aged twenty-two, was admitted on March 1, 1887, into St. Bartholomew's Hospital. He had been drinking the night before, and in a fight was butted by his opponent in the abdomen, his bladder being full at the time. He passed a night of great agony, and was brought in a cab to the hospital the following morning; but he was then suffering very little shock, and walked into the surgery with the assistance of two friends. He complained of pain in the lower part of the abdomen, and of having been unable to pass any urine since the blow, although his bladder was uncomfortably full at the time. The perineum was natural, and there was no history of stricture. On passing a catheter no urine flowed, although the point was ascertained to be in the bladder by the finger in the rectum. On depressing the handle the catheter was felt to free itself with a jerk, and its point could be then felt more plainly than natural through the abdominal walls. Bloody urine now escaped, the flow varying with respiration. About twelve hours after the injury Mr. Walsham opened the abdomen, and, having discovered an intraperitoneal rent in the posterior wall of the bladder, sewed it up with nine Lembert sutures. The sutures were passed through the muscular and peritoneal coats only, and one was placed above and below the upper and lower angles of the wound, respectively. The bladder having been forcibly injected with eight ounces of boric-acid solution and found water-tight, the peritoneum was irrigated with about two gallons of warm boric-acid solution, and the abdominal wound closed as in ovariotomy. A catheter was left in the bladder for two hours, and the patient subsequently reminded to pass his urine every four hours. There was little shock, and the patient recovered. Daily notes were given at length. The author remarked that there had now been 17 cases in which abdominal section had been performed for rupture of the bladder, 3 extraperitoneal and 14 intraperitoneal. Of the 3 extraperitoneal cases 2 died and 1 recovered. In the successful case the wound in the bladder was secured to the abdominal wall, but not sutured. In the fatal cases death was due to shock. The rent in one was found securely sutured at the post-mortem examination; in the other the rupture had not been discovered on opening the abdomen. Of the 14 intraperitoneal ruptures, the rent in the bladder was sutured in 11, and in 3 a drainage-tube was placed in the wound, but no sutures employed. Of these 3, 1 recovered and 2 died, death being due to peritonitis and suppression of urine, respectively. Of the 11 cases where the rent in the bladder was secured by sutures, 5 recovered and 6 died, death being due in 3 cases to peritonitis, in 2 probably to shock, and in 1 to hemorrhage from a perineal incision employed for exploration. In the 3 cases of peritonitis the sutures had given way in 1, and a leakage had occurred in the lower part of the wound in the other 2. In the 5 successful cases Lembert sutures were employed and the peritoneum was washed out, and in only 1 was a drainage-tube used. The author discussed (1) the advisability of early operation; (2) the importance of using a suture which would not become softened too soon, and of ascertaining before closing the abdominal wound that there was no leakage from the bladder; (3) the cleansing of the peritoneal cavity; (4) the unadvisability of a preliminary incision in the perineum, or of a subsequent incision in that region for the purpose of drainage; and (5) the question of tying in a catheter after the operation, which he decided in the negative.

Creasote in Phthisis.—The treatment of phthisis by the internal administration of creasote has recently been employed in Professor Koshlakoff's clinic in St. Petersburg, the results obtained forming the subject of a paper by Dr. V. T. Bushuyeff. According to this author, the creasote treatment of phthisis was originated by MM. Bouchard and Gimbert, who in 1877 published ninety-three cases treated in this way, of which number fifty-four had been greatly benefited by it (*The Lancet*). Since then several physicians have published accounts of successful results. Among the more recent writers on the subject, Sommerbrodt, Fraentzel, and Lublinski are mentioned. Creasote has been prescribed in various forms—with wine, glycerine, fish oil, and in capsules and pills. The quantity given by Dr. Bushuyeff was usually about three drops of creasote during the twenty-four hours. The number of cases in which it was given was twenty, and the duration of the treatment from one to six months. Of these twenty cases, ten were in the first stage, six in the second, and four in the third. In all those in the first stage, the treatment was followed by a marked improvement. Four out of the six in the second stage were benefited, but none of those in the third stage. The improvement was shown by the diminution of the cough and of the expectoration, by the decrease or entire arrest of the fever and sweats, by the increase of the body-weight, and in two cases with laryngeal trouble by the cessation of pain and the diminution of the laryngeal swelling. In five of the cases in the first stage, it may almost be said that the creasote produced a cure, because the dulness and bronchial respiration, as well as the râles, ceased. The creasote never produced any undesirable effects, except in one instance, in which a patient in the last stage of the disease took by mistake six drops (instead of three) for three days. This was followed by a stoppage of the diarrhœa, general anasarca, and a large quantity of albumen in the urine with casts, and some red blood-corpuscles. With milk diet these morbid symptoms rapidly disappeared. Dr. Bushuyeff analyzed the constituents of the urine in some of the cases, and found that the nitrogeneous metabolism in phthisical patients, as indicated by the ratio of the nitrogen of the partially oxidized nitrogeneous constituents of the urine (urates, creatin, etc.) to the nitrogen of the urea, is less than in healthy persons, and that this ratio becomes still smaller when creasote is taken. The smallest ratio he found in his patients was 1 : 10.6 before taking creasote, and 1 : 7 while taking it. In healthy persons it is, according to Bartonovski, from 1 : 15 to 1 : 17.

Silk Stockings were first worn by the French King, in 1543; and in England by Queen Elizabeth, in 1561. Tobacco was first brought from Virginia in 1583.

THE TONGUE IN DISEASE.

DR. W. H. DICKENSON has recently delivered a series of lectures upon "The Tongue as an Indicator of Disease." His remarks are based upon a study of a very large number of hospital cases. In most instances the patients suffered from severe and fatal illnesses, and microscopical examinations of the tongue were made.

Dr. Dickenson's results are definite and valuable in certain limits, but they do not throw much light upon the many variations in the appearance of the tongue during minor and chronic ailments.

The lecturer makes a classification of tongues, based on the excess or absence of epithelial coat, its congestion, and its condition of moisture or dryness. The terms which he uses are for the most part such as are old and well known. The term furred, however, is used in a restricted sense, it being applied only when the papillæ are elongated and separated so as to give a shaggy appearance to the organ under examination. The term "plastered" tongue is also a somewhat new one, and is applied to those cases in which the covering is thickly laid on, as if with a trowel.

The following is the classification adopted:

1. Healthy. Moist.
2. Stippled. Dotted with white. (*a*) Moist, (*b*) dry.
3. Stippled and coated. Coat continuous in parts. (*a*) Moist, (*b*) dry.
4. Coated white. Coat continuous. (*a*) Moist, (*b*) dry.
5. Strawberry. Coated and injected, especially showing in fungiform papillæ.
6. White, plastered. Thick uniform coat, abrupt and striking.
7. Furred or shaggy. Greatly elongated papillæ. (*a*) Moist, (*b*) dry.
8. Incrusted, dry, brown. Thick felted dry coat over papillæ.
9. Furred or incrusted, becoming bare. Generally dry.
10. Denuded. Red. Absence of normal covering.
11. Red. Moist. Dry membranous covering.
12. Cyanosed.

In regard to the diseases which coat the tongue, it is seen at once that no hard and fast rule can be laid down. In some healthy persons, a coated tongue is normal; on the other hand, it sometimes happens that even in pneumonia, a disease which generally coats the tongue with unusual rapidity, this organ may remain clean.

As a general rule, it seems that the tongue is not affected by local, but only by constitutional disorders, of which latter pyrexia probably affects it most quickly.

The stippled or dotted tongue presents the first and slightest variation from health. It was rarely found present in fever, and rarely in acute disease. Heart disease was the most common disorder, but the dotted tongue was not found often in grave constitutional disorder.

The next step in the acquirement of coat is represented by the "dotted and coated tongue." This is also found chiefly in chronic disease, though a larger proportion of acute disorders, including acute rheumatism and typhoid fever, is found. The element of fever becomes now introduced.

The term "coated tongue" is the one most often and most indefinitely used by physicians in description of their cases. Dr. Dickenson applies it, in its restricted sense, to a tongue whose coat is simply an exaggeration of the dotted and coated. The "plastered tongue," "strawberry tongue," and "incrusted tongue," are further subdivisions of the ordinary coated tongue.

The "coated tongue," then, of Dr. Dickenson, shows an increased percentage of acute and febrile disease. Pneumonia and pleurisy were present in fifteen per cent. of cases, and typhoid almost as often. Saliva now begins to be secreted less abundantly, and the dry forms are more frequent.

The "strawberry tongue" was observed in typhoid, pneumonia, and perityphlitis, as well as in scarlatina.

The "plastered tongue" is believed by Dr. Dickenson to be a very well-marked and striking form of lingual disturbance. "Clinically," says our writer, "this tongue never fails to arrest attention; it is the ensign of recent acute febrile disease. The chronic coated tongue is distinguishable from the plastered by its dirtier color and the less vivid apposition of white and red. Of 32 cases of the plastered tongue, the table shows 8 of pneumonia; 3 of acute bronchitis; 3 of acute rheumatism; 6 of typhoid; and 4 of other acute febrile affections. Pyrexia was marked in 18 cases, while the general average of temperature was 101.6°, a higher level than has yet appeared, save with the strawberry tongue, a nearly allied condition. Prostration, mostly such as belongs to the febrile state, was recorded in 8; while the increased proportion of patients on liquid diet bears testimony to the same association. The saliva was noticeably deficient in a larger proportion of instances than with any tongue yet before us, save the small strawberry class."

In this connection an interesting table is given, showing the relation of body-heat to the development of the lingual epithelium.

Relations of Body-heat to Coating of Tongue.

Class of tongue.	Percentage with pyrexia.	Average temperature.
Stippled	4.9	98.5°
Stippled and coated	8.6	98.7°
Coated, moist	18.7	99.1°
Coated, dry	30.0	99.5°
Strawberry	57.1	102.0°
Plastered	53.1	101.6°

The "furred or shaggy tongue" is generally dry. In a few cases in which it was found moist, the patients were old and suffered from constipation. The dry, furred tongue often occurs when the coated or incrusted tongue begins to shed its excess of epithelium. It is largely the result of absence of friction and moisture. The class of diseases in which it is observed does not present any uniformity.

The "incrusted, dry, and brown tongue" is brown because of lack of moisture. This form only appears in serious asthenic states. It is often spoken of as the "typhoid" tongue, and it is seen in advanced stages of typhoid, as well as of pyæmia, pneumonia, and phthisis. But pyrexia is not necessary to its production. It occurs in comatose states and in cancer, pernicious anæmia, and Bright's disease.

The "bare, red, and dry tongue" is seen as the result of exhaustive discharges, especially of pus, and it is linked with the constitutional state described as hectic. It occurs in chronic diarrhœa and in dysentery, both acute and chronic. It occurs in chronic disorders oftener than in acute, and it may or may not be associated with pyrexia.

The "cyanotic tongue" was found in venous congestion from heart disease, in albuminuria, and in pyrexia.

THE HEALTH OF NEW YORK AND LONDON.

Dr. Roger S. Tracy, Registrar of Records of the City Board of Health, has prepared a report upon the relative mortality of London and New York. This report is based on the vital statistics of London for 1886, and of New York for 1887. The death-rate in the former city is 20 per 1,000; in New York, 26 per 1,000. Analysis of the figures shows that the chief causes of the excess of mortality in New York are diphtheria and croup, diarrhœal diseases, phthisis, and diseases of the kidneys.

The causes of death which are more common, proportionately, in London, are rheumatism and gout, heart disease and aneurism, cancer, convulsions, apoplexy, brain and nervous diseases, whooping-cough, and measles.

It will be seen that the diseases which cause excess of mortality in this city affect especially children. On the other hand, the excess of deaths from phthisis and kidney disease is due, in part, to the tendency to these diseases of our large Irish population. Foreigners, in general, who bring with them the generous drinking habits of their native lands, show a liability to develop renal and liver troubles.

The conclusions of Dr. Tracy are:

1. That the excess of mortality in New York, as compared with London, is due chiefly to diphtheria and croup, diarrhœal diseases, phthisis, and kidney diseases.

2. That if the death-rate from these diseases were the same in New York and London, the mortality from all other causes remaining as at present in both cities, the general death-rate in the two cities would be almost precisely the same.

3. That the overcrowding in New York (16.37 persons to a dwelling, in 1880, as compared with 7.8 in London), and the trying climatic conditions, render it very improbable that the death-rate of this city can ever be reduced as low as that of London.

With regard to the last conclusion, it must be said that, despite our crowded condition, diphtheria is the only zymotic disease which New York develops in great excess. In some years the mortality from scarlatina and small-pox has been greater, proportionately, in London than in New York.

News of the Week.

Medical College Commencements.—The Jefferson Medical College held its annual commencement on April 5th, and graduated a class of one hundred and eighty-eight.

The Southern Medical College on February 29th graduated a class of thirty-two.

The Memphis Hospital Medical College held its eighth annual commencement on March 1st, and conferred degrees on fifty-four graduates.

The Medical Department of the Arkansas Industrial University held its commencement on March 1, 1888, and graduated twenty men as physicians.

The Atlanta Medical College on March 1st graduated a class of fifty-four, out of fifty-six applicants.

The Medical College of Indiana graduated a class of twenty-five on March 1st, and The Central College of Physicians on February 28th conferred degrees on five graduates.

The St. Louis College of Physicians and Surgeons graduated a class of thirty-seven on March 3d.

The Missouri Medical College graduated sixty-six students at its forty-seventh annual commencement on March 6th.

The St. Louis Medical College graduated a class of sixteen on March 6th.

The Beaumont Medical College graduated thirty-three students at its commencement on March 15th.

The Detroit College of Medicine had thirty graduates at its commencement on March 20th.

The Western Pennsylvania Medical College held its annual commencement on March 24th, and graduated a class of thirty-four.

The commencement exercises of the Medical Department of Tulane University of Louisiana were held on March 28th. There were seventy-five graduates in medicine and pharmacy.

A New Medical College has been established in Detroit, to be known as the Michigan College of Medicine and Surgery. It is only a short time ago that the two medical colleges formerly in existence there were united. But the union seems to have been rather conjugal than platonic, for as a result of the amalgamation we now have a new institution. The best evidence of its prospective usefulness and success we see in the appointment of the brilliant editor of the *Medical Age* as Professor of Pathology and Practice of Medicine.

Another College Raising its Requirements.—We are glad to notice that the Medical Department of the Western Reserve University, beginning next fall, will require an attendance upon three years of graded course instruction as a condition for admission to the applicants for the degree of M.D.

To Stop Illegal Practising.—The Essex County Medical Society has begun a war upon the physicians practising in Newark, N. J., who have not proper diplomas to practise, and the Committee on Illicit Practice has been directed to secure the indictment by the Grand Jury of three persons who have, it is alleged, no legal status as physicians.

The late Dr. Andrew B. Van Horne.—Dr. Van Horne, recently of Colorado Springs, died on March 31, 1888, at Orange, N. J. The doctor was a graduate of Yale, and received his medical education at the College of Physicians and Surgeons, New York, graduating in 1880. He was house surgeon at Charity Hospital. Shortly after leaving the hospital symptoms of pulmonary phthisis showed themselves and he left his home, Jersey City, for Colorado Springs. He returned East last summer somewhat improved, but his health steadily declined until his death. Dr. Van Horne was always very popular on account of his sunny temperament and genial manner; as a student and hospital interne he is well remembered as industrious and painstaking.

The late William B. Goldsmith, M.D.—At a meeting of the New England Psychological Society, held on April 10th, the following resolutions were unanimously adopted: The New England Psychological Society, having learned the painful news of the death of a highly valued and beloved member, Dr. William B. Goldsmith, Superintendent of the Butler Asylum at Providence, R. I., recalls, with a deep sense of its great loss, his high character, exceptional ability, and refined and genuine nature.

Resolved, That such has been the influence of his opinions, based upon his solid attainments and great devotion to his work, that broader views of the treatment of the insane and deeper insight into mental disease have come to many of us, his fellow-workers.

Resolved, That by his death is lost a tried and considerate friend, a judicious and helpful counsellor, and a courteous and cultivated associate.

Resolved, That the Secretary be requested to communicate these resolutions to the family of our deceased friend, and to extend to them our profound sympathy in their sorrow. Walter Channing, M.D., *Secretary*.

Tennessee State Medical Association.—This Society met in annual session at the United States Custom House at Knoxville, April 10th, the President, Dr. P. D. Sims, of Chattanooga, in the chair; Dr. E. Nelson, of Knoxville, Secretary. Twenty-three new members were elected. The first paper read was by Dr. Richard Douglas, of Nashville, Tenn. His subject was "Laparotomy Practically Considered;" he also reported a number of cases. The operation was discussed by seven different gentlemen, and the operation advocated. "The Germ Theory of Diseases" was the title of a paper by Dr. H. P. Coile, of Knoxville. "The Antiseptic Treatment of Wounds" showed the ability of Dr. Duncan Eve, of Nashville, as an investigator, in an able paper. "Fissures and Ulcers of the Rectum," by T. J. Hoppel, of Knoxville. "Diphtheria," a paper by Dr. John M. Boyd, was so well appreciated that the author was given a special vote of thanks. In the evening a popular session was held at Straub's Theatre, at which the élite of Knoxville were present. Dr. John M. Boyd, of Knoxville, made the welcoming address to the visiting doctors. The President, Dr. P. D. Sims, of Chattanooga, after expressing appreciation of the hospitality shown them proceeded to his address on the subject, "Materialism in Disease." He said that medicine furnished two extremes of human thought. One looked for all causes of disease among agencies mysterious and mythical, the other rejected everything which does not admit of physical, tangible demonstration. It is natural to inquire for the cause of the phenomenon, and at present this is being done in an intelligent manner. Our ancestors sought in the planets and animals the causes of their afflictions. Disease is only the result of violation of immutable laws. It is for a moral purpose and used in the economy of nature. With the present means of scientific investigation, the time is coming when we can scrutinize every disease as a specific condition. All contagious diseases must be introduced from without, for no amount of filth will produce them unless some germ exists or is brought in. We can make man either strong or weak, but cannot make an organic unction any more than man can turn monkey. A disease is too often treated instead of the patient. It must be regarded as a condition in the sick and worked on accordingly. What is life but the productive power of creation, and that the work of God? The enlightened physician of to-day cannot believe in materialism and make a practical and thorough success of his profession. The doctor was honored with the closest attention throughout the hour of his address.

In the second day's session "The Philosophy of Fever" was the first paper, read by Dr. C. W. Beaumont, of Chattanooga. Dr. G. A. Baxter, of Chattanooga, read on "Infant Feeding;" Dr. G. F. Glenn, of Nashville, on "Syphilis and Marriage." "Treatment of the Insane" was dealt with by Dr. C. C. Fite, of Knoxville, Tenn.; "The Eye and its Abuse," by Dr. T. F. Smith, of Chattanooga; "Resection of the First Metatarsal Bone of the Foot for the Cure of Bunion," by S. T. Armstrong, M.D., of New York; "Some Observations and Thoughts on General Paralysis," by Dr. M. Campbell, of Knoxville; "Cholera in Tennessee," by Dr. J. B. Lindsay, of Nashville.

The Committee on Legislation reported a bill for presentation to the legislature for the suppression of quackery.

The election of officers resulted as follows: T. B. Hoppel, of Trenton, President; C. M. Drake, of Knoxville, First Vice-President; C. W. Beaumont, of Clarksville, Second Vice-President; Dr. E. Nelson, of Chattanooga, Secretary; and R. Cheatem, of Nashville, Treasurer.

A resolution from the W. C. T. U., requesting the Association to discontinue the use of alcohol in medicine, was rejected.

A reception was given in the evening by the citizens and local profession of Knoxville, in the rooms of the Chilhowee Club.

Remedy for Myalgia.—An old and well-known formula combined with lanoline had such a quick and favorable effect in myalgia of the scapular and brachial regions, that I feel safe in offering it to the profession. ℞. Hydrate chloral, gum camphor, āā ℥ ss. Mix well, until liquid, and add lanoline, ℥ j. M. S.—Rub well over painful parts. To show what lanoline can do, it fully relieved the pain in six hours, and had the constitutional effects of chloral as fully as if the person had taken gr. xx.–xxx. per mouth. Only two appplications were used, and only a limited portion of the salve.

The English Drank some $10,000,000 worth more alcohol in 1887 than in 1886, the increase being chiefly in beer.

The Publication of the Transactions of the recent Medical Congress at Washington is progressing, and it is probable that at least three volumes will be ready for delivery early in May next.

Food Inspection.—The United States Senate has passed the bill providing for the inspection of meats for export, and prohibiting the importation of adulterated or unwholesome foods, or of vinous, spirituous, or malt liquors adulterated or mixed with any poisonous or noxious chemical drug or other ingredients injurious to health. The bill further prohibits the importation of diseased or infected animals, or those exposed to disease or infection.

A Bill Incorporating an Institute for Teaching "Christian Science" has passed our learned legislative body at Albany.

A Righteous Judge.—We take pleasure in commending the just and sensible course taken by Judge Barrett in setting aside the verdict of the sheriff's jury in the case of Miss Coffin. The evidence plainly showed that the young woman was insane; but the defence had secured a legal expert at browbeating medical witnesses, and the result was a verdict of not insane. The judge sets this aside as contrary to the evidence.

The Italian Surgical Congress held a successful meeting on March 27th at Naples. The papers read included one by Professor Andrea Ceccarelli, of Parma, on "Tannin in the Treatment of Tuberculous Affections," in which he set forth the good effects resulting from its use, local as well as internal. Dr. Ambrosio, of Naples, read some interesting notes on the "Transplantation of Pieces of Aseptic Sponge in the Cure of Ulcers and Wounds;" and after him came Professor Lampiasi, of Trapani, on "Bacteriological Researches in Tetanus," who professed to have found and cultivated the micro-organism of tetanus, by which he has been able to produce genuine tetanoid symptoms in many animals. Dr. Ernesto Tricomi, of Rome, read a paper on "Septicæmia and Pyæmia in Man," contending for a variety of septicæmias all due to diverse bacteria. Dr. Neri, of Rome, read a paper on "Micro-organisms in the Surgical Wards of the Roman Hospital," in which he showed that the renewal of air in a hospital should be effected from floor to ceiling, and not, as is invariably done, from ceiling to floor. Professor D'Antona followed with a paper on "Transverse Fracture of the Patella, with Resection and Suture," which led to a long discussion; Bozzini and Vercelli favoring tenotomy; Paci, of Pisa, myotomy, to bring together the fractured margins of the patella; Postemski, the hooks of Malgaigne; while Ceci of Genoa's metallic suture was the method approved by D'Antona himself. Another interesting debate was that started by Caselli on the revival of the abandoned metallic sutures in osseous fractures, in which the leaders of the Congress all took part.

Thieving Medical Students.—Teachers of medical students have been compelled to notice a most extraordinary tendency to forget the distinctions between *meum* and *tuum* in the class of persons under them. Some time ago a large amount of drugs and appliances was stolen from Bellevue Hospital; and, quite recently, a student of the University Medical College stole some expensive apparatus from the Loomis Laboratory. A few lectures on the fundamental principles of ethics might be a profitable investment for medical, and perhaps other, colleges. For we fancy that the propensity to steal is due rather to irresponsible adolescence than to the special influences of medical study. We may remark in this connection that it is with a certain feeling of satisfaction that one chronicles the fact of the theft of apparatus valued at $1,000 from a medical college. There have been times and colleges when $1,000 would have purchased the whole plant of the institution. There may be such in this country now. If so, they at least need no lectures on property rights, and need not worry over possible $1,000 thefts. "*Cantabit vacuus latrone viator.*"

Dr. Martineau, the well-known gynecologist of Paris, died on March 13th in the fifty-third year of his age.

William Benjamin Goldsmith, Superintendent of the Butler Hospital for the Insane, at Providence, R. I., died on March 21st of acute pneumonia, aged thirty-four.

The State Medical Society of Alabama has practically adopted the new code of ethics. That is to say, by recent legislation, every person who passes the examination of its Board of Examiners becomes a member of the Society. A medical education qualifies a man to be legally a doctor and a member of the Society, be he homœopath or regular. If it is consistent, the American Medical Association cannot now refuse delegates from the New York State Society and accept those from Alabama. We await the action of the learned body in the matter with much interest.

The Late Mr. Matthew Arnold wrote a poem entitled "The Wish," in which he indicated the kind of death-bed he would desire to have. He makes the following somewhat unpleasant allusion to the medical profession and the clergy:

> "Nor bring, to see me cease to live,
> Some doctor full of phrase and fame,
> To shake his sapient head, and give
> The ill he cannot cure a name.
>
> "Nor fetch, to take the accustomed toll
> Of the poor sinner bound for death,
> His brother doctor of the soul,
> To canvass with official breath."

A Striking Feature of journalism just now is the rapid increase in the number of sanitary journals. For many years the esteemed *Sanitarian* held the field alone. Now we have *The Sanitary News*, *The Sanitary Era*, *The Journal of Health*, *The Annals of Hygiene*, and now comes another new journal, *The Prophylactic*, a monthly journal, published by M. B. Playter & Co., of this city.

Treatment of Epithelioma by Marsden's Paste.—Dr. A. R. Robinson treats epithelioma, where the disease has not progressed far enough to involve the glands, in the following manner, and promises a good result. Make a paste—"Marsden's paste." ℞. Ac. arseniosi, gum acaciæ, āā ʒ j. Sig.—Apply enough to cover diseased tissue by means of rubber adhesive plaster, and leave on for about sixteen hours. Then wash with warm water and apply a simple dressing, as ung't. zinc. ox., or vaseline, for about a week. If all the pathological tissue be not destroyed, make further applications in the same way.—*Canada Lancet.*

Medical College Changes and Appointments.—Dr. Joseph Taber Johnson has been made Professor of Gynecology in the Medical Department of Georgetown University; Dr. P. J. Murphy has been appointed Professor of Obstetrics. Dr. Nicholas Senn, of Milwaukee, Wis., has been appointed Professor of the Principles of Surgery and Surgical Pathology in the Rush Medical College; Frank T. Andrews, M.D., has been appointed Professor of Histology in the Chicago Medical College; and Henry F. Lyster, M.D., of Detroit, has recently been appointed to the Chair of Practical Medicine in the University of Michigan, made vacant by the death of Professor A. B. Palmer.

Death of a Medical Editor.—Dr. Robert Hippolite Brochin, the distinguished editor-in-chief of the *Gazette des Hôpitaux*, died on March 25th in the eightieth year of his age.

The Legislature of Maryland made an appropriation of $3,000 to the College of Physicians and Surgeons of Baltimore, and gave $1,500 a year for two years to the Good Samaritan Hospital.—*Maryland Medical Journal.*

A Law to Regulate the Practice of Medicine in Maryland.—The bill to regulate the practice of medicine in Maryland has passed both branches of the Legislature, and, as soon as it receives the Governor's signature, will become a law.

A New Large and Magnificently Appointed Hospital has recently been opened at Genoa. It is known as the Hospital of St. Andrew the Apostle.

Obituary.

CORNELIUS REA AGNEW, M.D.,

NEW YORK.

The medical profession of this city and country has met with an irreparable loss in the death of our esteemed friend Dr. Agnew. In the full tide of active professional work, he was stricken with perityphlitis, which rapidly led to perforation of the vermiform appendix, and consequent peritoneal abscess. The disease was at once recognized by Dr. Delafield, and Dr. Sands was called to operate. The operation resulted in the evacuation of pus, and for a time hope was revived in the hearts of his many friends; but, despite all their efforts, symptoms of general peritonitis manifested themselves, and death occurred on Wednesday afternoon. The illness extended scarcely over a week.

Dr. Agnew was born in this city, August 8, 1830, and was of Huguenot, Scotch, and North Irish extraction.

Prepared for college by William Forest, of this city, at the age of fifteen Dr. Agnew entered Columbia College, from which he was graduated in 1849. He then began the study of medicine under Dr. J. Kearney Rogers, who for many years had been attached as Surgeon to the New York Hospital and the New York Infirmary, and was also Professor of Anatomy in the old College of Physicians and Surgeons. In 1852 he received his diploma from the College of Physicians and Surgeons, and soon after was appointed House Surgeon to the New York Hospital, and then its Curator. Then he accepted the position of Surgeon to the Eye and Ear Infirmary, but made it a condition that he should first go to Europe to complete his studies. He accordingly went to Dublin, where he became a resident pupil of the Lying-in Asylum, and attended the clinics given by William Wilde at St. Mark's Eye and Ear Hospital. Then he went to London, where he attended the clinical lectures of William Ferguson, and walked the hospitals. From London Dr. Agnew went to Paris, where he studied the practice of Velpeau, Ricord, Sichel, and Demarres in diseases of the eye, and of Hardy in diseases of the skin.

Returning to New York in 1855 he started in practice for himself. The next year he married Mary, daughter of Lora Nash, a merchant in this city. In 1858 Governor E. D. Morgan appointed him Surgeon-General of the State of New York, and at the outbreak of the war the Governor appointed him Director of the State Volunteer Hospital, New York. When the United States Sanitary Commission was organized Dr. Agnew and Dr. Elisha Harris were unanimously elected to the Commission. About this time he resigned his position as Surgeon to the Eye and Ear Infirmary that he had been holding ever since his return from Europe. He was regarded as an authority in the United States Sanitary Commission, and although he had a large private practice he devoted all the rest of his time, at great personal sacrifice, to the succor of the soldier. The life-saving work of the Commission at Antietam, the battles of the Wilderness, and the relief to the wounded and sick soldiers who returned from Southern prisons were made so successful principally by the carefully arranged plans of Dr. Agnew, and which were superintended by him.

Dr. Agnew was one of the four gentlemen who founded the Union League Club in this city that gave so great material assistance to the Government during the war, and he became one of its Vice-Presidents.

In 1866, at the request of the Faculty of the College of Physicians and Surgeons, he established an ophthalmic clinic there, and in 1869 he was elected Clinical Professor of Diseases of the Eye and Ear. The following year he organized the Brooklyn Eye and Ear Hospital, and also the Manhattan Eye and Ear Hospital, the latter in this city. He had been appointed in 1865 one of the Managers of the New York State Hospital for the Insane, at Poughkeepsie, and was twice reappointed to that office.

As early as 1859 Dr. Agnew was elected a Trustee of Public Schools in this city, and was made President of the board. Several years later he was selected a Trustee to organize a School of Mines in Columbia College, and in 1874 he became a Trustee of that college. In 1872 he was chosen President of the Medical Society of the State of New York. He was Secretary of the first Sanitary Reform Association organized in this city, and one of the committee which made the first draft of the health laws of the city. He was for many years a member of the Century Club, and belonged to a number of medical and scientific societies, among which are the following: The Medico-Chirurgical Society of Edinburgh; New York Academy of Medicine, New York Pathological Society, Medical and Surgical Society of New York City, American Ophthalmological Society, of which he had served as President; American Otological Society, New York Ophthalmological Society, of which he was one of the founders; International Ophthalmological and Otological Societies, County Medical Society, and New York Academy of Sciences. He was a fluent lecturer, and was widely known as an authority on ophthalmology. He made valuable contributions to medical literature, among which were "A Contribution to the Surgery of Divergent Squint," "Trephining the Cornea to remove a Foreign Body," and "Canthoplasty as a Remedy in certain Diseases of the Eye."

Dr. Agnew was beloved by all who knew him, and his name was held in the highest esteem wherever it was known. He was of a modest and retiring disposition, yet he had charming social qualities. Few physicians in this country united so much learning with so many noble traits of character, and his death will be mourned by scientific men and by people in all walks of life.

Society Reports.

FRENCH SURGICAL CONGRESS.

Third Annual Session, held in Paris, March 12 *to* 17, 1888.

Professor Verneuil, President, in the Chair.

(Special Report for The Medical Record.)

(Continued from page 423.)

Thursday, March 15th—Fourth Day.

The members of the Congress passed the forenoon of this day in visiting the different hospitals and surgical clinics of Paris, witnessing the operations and inspecting the institutions. In the afternoon they visited the Pasteur Institute, the Morgue, the Museum of Hygiene, and Professor Cornil's histological and bacteriological laboratories.

In the evening a banquet was given at the Hôtel Continental, which was attended by most of the delegates.

Friday, March 16th—Fifth Day.

The subject proposed for discussion at this session was the

TREATMENT OF EMPYEMA.

M. **Le Fort** reported two cases at that time under treatment in his service at the Hôpital Necker. The first case was cured, but there remained a fistulous tract extending a distance of over twelve inches toward the upper part of the thorax. In the second case,

ESTLANDER'S OPERATION

had been twice performed without any definite result. He had been in the habit of measuring the progress of closure of the cavity by means of injections. On the last occasion on which this was done, after about three ounces had been injected, the patient suddenly lost consciousness. He was restored by means of electricity, but was found to have complete paralysis of the left arm and partial paralysis of the leg on the same side, with considerable mental disturbance.

M. **Thiriar** had performed

RESECTION OF THE RIBS

nineteen times on thirteen patients during the past four years. Of these cases eleven were cured, one died of acute pleuro-pneumonia, and one passed out of sight before the fistula had completely closed. He had performed the same operation in two cases of

INTERLOBULAR PLEURISY.

In this affection there is a purulent collection formed between two contiguous lobes of the lungs, and eventually the abscess opens into the lung, a purulent fetid suppuration being established. The patients become more and more emaciated, and finally die. In these cases Estlander's operation is of very great service as a preliminary to

PNEUMOTOMY.

The speaker related two cases of this nature in which he had resected the ribs, opened the abscess-cavity through the pulmonary tissue, washed it out, and drained it thoroughly. The patients made a good recovery. In performing this operation the surgeon should not be timid. It was far better to resect two ribs too many than to fall short by one.

M. **Jules Boeckel** had performed this operation twelve times, and had had nine recoveries and three deaths. In two of the cases regarded as cured, however, there still remained a small fistulous tract.

M. **Delorme** thought that the indications for

THE LETIÉVANT-ESTLANDER OPERATION

were far from being as well defined as it was desirable that they should be. The unfavorable results which had followed the operation in certain cases, where success had been looked for and promised, had brought it into more or less disrepute. The cause of this failure in many instances was the fact that the pleural cavity was too large to be closed by the falling in of the thoracic wall deprived of its bony support. A depression of three centimetres was the most that could be obtained by the operation. If, however, in addition to the resection of the ribs, the soft parts were divided throughout the entire length of the suppurating cavity, they could be folded in and thus be made to obliterate entirely the pleural space.

M. **Vieusse** said that the indications for

THORACOPLASTY

were to be found in the extent, age, and situation of the suppurating cavity, in the degree of retraction of the chest-wall, and in the general condition of the patient. Success might at least be hoped for if the suppuration had existed for six months or longer, if the cavity were not of very great extent, if there were no more retraction of the chest-wall going on, and if the patient were in a fair condition of general health.

M. **Berger** called attention to the

DANGERS OF RESECTION OF THE RIBS.

He had formerly regarded the operation as perfectly safe, even if not always curative, but he had recently had two cases of sudden death following it, and had in consequence become more cautious. In patients debilitated by age or long suppuration, or in whom the whole extent of the pleural cavity was involved, he advised that (1) the ninth and tenth ribs be left intact, in order to interfere as little as possible with the respiratory movements; and (2) that only a few ribs be resected at a time, thus obtaining a gradual closure of the suppurating cavity.

M. **Bouilly** had performed the operation thirteen times in patients ranging from twelve to thirty-one years of age. The best results had been obtained in individuals between the ages of eighteen and twenty-one years, in whom the chest-walls were more flexible and accommodated themselves more readily to their new position.

M. **Ollier** spoke of the modifications in the technique of the operation occasioned by the age of the patient. In the adult an extensive operation was demanded, but in the child a narrow section only of the bony wall should be removed. On account of the elasticity of the thoracic parietes this would allow of a sufficient sinking in, while the danger of an arrest of development of the ribs would thereby be reduced to a minimum. In certain cases the bone was reproduced so rapidly as to necessitate a second operation. In young and robust subjects in whom this was to be feared it was better to prevent it by destroying the periosteum for a certain distance.

MM. Kirmisson, Levrat, and Fauvel reported cases of this operation which were of interest on account of peculiar circumstances attending them.

M. **Poncet** read a paper on

RESECTION OF THE URETHRA

in the treatment of certain forms of stricture. He preferred external urethrotomy in most cases, but had occasionally resorted to urethrectomy, and had been well pleased with the results obtained.

M. **Bazy** reported two cases of

FOREIGN BODY IN THE BLADDER.

In the first, after crushing a calculus, he had found the nucleus to consist of a tangled piece of linen thread, about six yards in length. This patient was a woman, aged sixty-six. The second patient, a man, aged forty-five, had introduced a thin rod of pork, about five inches long, into his urethra, and, having slipped from his fingers, it passed into the bladder. This was followed by complete retention. When M. Bazy saw the man, a few days later, he passed a catheter and drew off a large quantity of horribly fetid urine, worse than any he had ever seen in cancer of the bladder. The foreign body was removed, the bladder was washed out, and in a few days the patient was passing perfectly limpid urine.

M. **Ehrmann** presented a communication on

PALATOPLASTY.

He reported twenty operations for cleft palate, in seventeen of which a successful result was obtained. He thought the most favorable age for the operation was between two and four years.

M. **Guyon** read a paper on

HYPOGASTRIC SECTION,

in which he recounted the recent modifications in the technique of the operation, which he had found to be decided improvements.

M. **Segond** read a communication on the surgical treatment of

HYDATID CYSTS OF THE LIVER.

The first thing to do, he said, in the case of a supposed hydatid cyst, was to aspirate the tumor. This was useful as a diagnostic measure, and might be curative. If there were a reaccumulation of fluid, it would be necessary to make at once a large incision into the cyst. The operative details differed according as the cysts were located at the antero-inferior, antero-superior, postero-inferior, or postero-superior part of the liver. The rules for incision in the first three classes of cases were pretty well established, but for reaching the subdiaphragmatic tumors, two routes had been recommended, viz., the abdominal and the thoracic. The speaker had performed the latter operation twice with success, and thought that it was the better method.

M. **Maunoury** related two cases of

SUBDIAPHRAGMATIC HYDATID CYSTS

treated by a posterior pleural incision. In the first case' the operation was followed by an acute suppurative pleurisy, but in the second case, the two pleural surfaces were united by suture before the puncture was made, and the wound healed without accident of any sort.

M. **Accolas** reported a case of

ABSCESS OF THE LIVER.

treated successfully by Little's method of direct incision.

M. **Pozzi** reported a case of extirpation of a hydatid cyst, and described the method of

ABDOMINAL SUTURE

which he employed after laparotomy. He united first the peritoneum, and then the aponeurosis, separately, with catgut sutures cut off and left permanently in the tissues, and after this approximated the integument and subcutaneous tissues by means of silk or coarse catgut.

M. **Horteloup** related a case of

ENTERORRHAPHY

for the cure of an intestinal fistula involving the cæcum, following a perityphlitic abscess. After two unsuccessful attempts to close the artificial anus thus resulting, the speaker dissected away the gut, drew it outside, and closed the opening by nine interrupted sutures. The result was all that could be desired.

M. **Labbé** recounted a case of

FOREIGN BODY IN THE LARYNX.

An attempt to remove it by means of a median section of the thyroid cartilage induced asphyxia, and the child's life was saved only by an immediate tracheotomy. The foreign body, a metallic star with sharp points, was then extracted, and the patient made a rapid recovery.

M. **Tillaux** then read a paper on the

TREATMENT OF PSEUDARTHROSIS.

This accident, when occurring in the femur or humerus, is due almost always, he believed, to the interposition of muscular tissue between the ends of the bone. His treatment consisted in the excision of the muscular tissue, freshening of the ends of the bone, and immobilization. Osseous suture he condemned as not only useless but harmful.

M. **Picqué** related a case of

ANEURISM OF THE FEMORAL ARTERY

appearing rather suddenly in a woman, aged fifty-nine, who had had for some time an intermittent limp with lancinating pains in the lower extremity. A cure was obtained by ligature of the external iliac artery.

M. **Vincent** presented a communication on the relation between

HEMORRHAGE AND CHRONIC HEPATIC DISORDERS.

The occasion of his remarks was the death from secondary hemorrhage of a child upon whom he had performed a cholecystotomy. He thought that hemorrhage was always to be feared in operations upon subjects of chronic disease of the liver, and this even in cases in which there was no lesion of the larger vessels. This was in accord with the observations of M. Verneuil upon the casual relation between disease of the liver and epistaxis.

M. **Jalaguier** reported two cases of

HERNIA OF THE CÆCUM

in which a cure was obtained by the radical operation.

Saturday, March 17th—Sixth Day.

The subject for discussion at this session was that of the

RETURN OF CARCINOMA AFTER OPERATION,

the cause thereof, and the best means of prevention.

M. **Cazin** presented the statistics of the cases of cancer of the breast occurring in his own practice during the past twenty-five years. There were 102 operations for scirrhus, in 60 of which there was glandular enlargement. Of these patients, 3 died, 2 were lost sight of, 48 suffered a relapse, and 7 were definitely cured. Of 48 cases in which there was no glandular involvement, 1 died, 5 had disappeared, 8 were cured, and in 28 the disease returned. Of 120 cases of encephaloid carcinoma, the ganglia were involved in 80. Of these, 4 died, 4 were lost sight of, 5 were cured, and 67 relapsed. Of the 40 cases without glandular enlargement, 1 died, 5 could not be traced, 8 were cured, and 26 relapsed. In the cases in which the disease returned, this occurred from three months to seven years after operation. In all his operations he removed the axillary glands, whether they appeared to be involved or not, and also the lymphatics connecting them with the mammary tumor.

M. **Verneuil** maintained that

CANCER IS A CONSTITUTIONAL DISEASE,

and that the most that an operation can do is to secure for the patient a respite of greater or less duration. In support of this view he instanced the case of a lady who suffered a return of the disease in the cicatrix thirty years after amputation of the breast, and another case of epithelioma of the tongue, in which the disease recurred six and a half years after removal. As a preventive he advised a vegetable diet and the daily exhibition, for at least six months after operation, of arsenic and magnesia.

M. **Poncet**, basing his conclusions upon the results of his own cases, believed that

PRIMARY EPITHELIOMATA OF THE SCALP

were much more malignant than similar growths arising from transformation of sebaceous cysts. Of seven cases of the former upon which he had operated, all died within three years of a return of the disease, while in two cases of the latter a definite cure had been obtained in both. The following were his conclusions: 1, In cases in which there is an hereditary history of cancer, a return of the disease is certain; 2, involvement of the neighboring glands increases the tendency to relapse; 3, the best prophylaxis is an early and extensive operation; 4, in certain unfavorable cases an operation only hastens the fatal issue.

M. Boeckel presented the

STATISTICS OF ONE HUNDRED AND THREE CASES OF CANCER,

in various situations, removed by operation. Of these, 14 died, 77 had a recurrence of the disease within five years, and 12 were cured.

M. Polosson read a paper upon

DIFFUSE MYXO-SARCOMATA OF THE EXTREMITIES.

His conclusions were that, in the case of tumors of limited extent, an attempt at extirpation might be made, but in case of a very large growth, or of relapse after removal of a smaller tumor, the only hope for the patient lay in amputation of the member.

M. Labbé spoke more especially on the question of the

RECURRENCE OF BENIGN TUMORS.

In adenoma of the breast it was very common to see a return of the growth after simple enucleation. It was necessary in these cases to remove some of the tissue extending beyond the capsule, and when the tumor was of very large size the entire breast should be excised, and all the outlying islets of gland-tissue should be carefully sought for and cut out.

M. Richelot read a paper upon

CARCINOMA UTERI,

in which he related the statistics from his own practice. He had performed vaginal hysterectomy thirteen times, but in two of these cases an extension of the disease to the broad ligaments was discovered during the operation. Of the remaining eleven operations, five were followed by a recurrence of the disease, and six were successful.

M. Sabatier was opposed to any attempt to secure primary union after amputation of the breast for cancer. He believed that, if suppuration took place, some cancerous germs might be washed away which would otherwise be retained in the wound.

M. Mollière said that one of the principal factors in the recurrence of new-growths after removal was the age of the patient. In children the disease returned almost immediately; in adults it returned usually, though not so quickly; while in those over seventy years of age, one could generally count on a definite cure.

M. Galezowski read a communication on

EPITHELIOMATA AND MELANO-SARCOMATA OF THE EYE.

Malignant tumors of this organ occur with greatest frequency in the anterior portion, where the circulation is more active. The tumors remain for a long time single, but they may be propagated by direct contact to the overlying portion of the eyelid. It is possible, more often than is commonly supposed, to extirpate these tumors without sacrificing the eye.

M. Poncet read a paper on

INGROWING TOE-NAIL,

in which he maintained that this affection arose in consequence of an inequality in growth between the great toe and its nail.

M. Le Fort related four cases in which he had successfully employed

ELECTROLYSIS IN THE TREATMENT OF PSEUDARTHROSIS.

M. Petit then read a paper on

GASEOUS TUMORS OF THE NECK.

He had collected the reports of twenty-five cases of these cysts. These tumors may arise, he said, from a hernia of the mucous membrane of the larynx or trachea, occurring after puncture or incomplete rupture of the wall of the tube, or there may be an infiltration of air into the tissues following complete rupture of some portion of the air-tubes. He thought some of them were susceptible of cure, and suggested that an operation similar to the radical operation for hernia might be performed with benefit in certain cases.

M. Jeannel read a paper on

LONGITUDINAL OSTEOTOMY,

which he had performed several times, straightening thereby very marked curves and lengthening the bones.

M. Bories reported a case of

ERECTILE TUMOR

successfully treated by electrolysis.

M. Abadie presented a communication on the prevention of

SUPPURATION OF THE EYE FOLLOWING TRAUMATISM.

He advised the use of a subpalpebral douche after the receipt of any traumatism whatever, whether from injury or operation. The liquid used should be unirritating and aseptic, though it need not necessarily be antiseptic. If suppuration occurred in spite of this douche, he was in the habit of touching the centre of the suppurating portion with the very fine point of the galvano-cautery. If this were done every twelve hours, it would often save the cornea from otherwise certain destruction.

M. Fontan related a case of

TEMPORARY RESECTION OF THE UPPER JAW,

to facilitate the removal of a large naso-pharyngeal polypus. Within less than three weeks after the operation, the patient was able to eat solid food, and in seven weeks could crack nuts with his teeth.

M. Kirmisson reported two cases in which he had performed

RESECTION OF THE BONE,

in order to shorten the limb and compensate for loss of substance in the soft parts.

M. Reynier reported a case of

GUNSHOT WOUND OF THE STOMACH,

in which the patient recovered without operative interference.

After the presentation of a number of instruments, the result of

THE ELECTION OF OFFICERS

was announced. M. Larrey was elected President; M. Guyon, Vice-President; and M. Pozzi, Secretary.

The Congress then adjourned to meet on the first Monday in October, 1889.

Eucalyptol and Iodoform in Phthisis.—M. Edmond Habert has found subcutaneous injections of eucalyptol and iodoform useful in ordinary phthisis accompanied by bronchial catarrh, and also in emphysema and chronic bronchitis. Cough and expectoration are diminished; the general condition is improved; sleep and appetite are restored. There is, however, no diminution in the number of bacilli in the sputa. The following solutions are employed: ℞. Absolute eucalyptol, 5 grammes; oil of vaseline, 20 grammes. ℞. Absolute eucalyptol, 5 grammes; iodoform, 0.25 gramme; oil of vaseline, 20 grammes. Each Pravaz syringe contains 0.20 gramme of eucalyptol for the first solution, and 0.1 more of iodoform for the second. The doses, which gradually increase, vary from 2 to 5 centigrammes in twenty-four hours. The solution must be absolutely pure, and the syringe must be properly disinfected. The quantity of liquid injected should not exceed thirty or forty drops. The needle should be introduced a good way beneath the skin.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 5, 1888.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. W. W. KEEN, of Philadelphia, and Dr. Charles C. Godfrey, of Bridgeport, were invited to seats on the platform.

The Council recommended such alterations in the constitution as would permit of extension of the territorial limits to membership in the Academy. Action will be taken at a future meeting.

DRS. E. C. SEGUIN and R. F. WEIR presented

A CONTRIBUTION TO THE DIAGNOSIS AND SURGERY OF CEREBRAL TUMORS.

The first part of the contribution was devoted to the relation of a successful case. The patient was a man aged thirty-nine, a German by birth, a resident of Bridgeport, under the care of his family physician, Dr. C. C. Godfrey. The man was brought to Dr. Seguin's office during his absence, August 12, 1887, but was seen by Dr. Booth. There was no history of gonorrhœa nor of chancre. It was learned later that his mother died of scirrhus of the liver. There was no history of epilepsy during childhood. He was perfectly healthy until the autumn of 1882, when he had malarial fever. During this illness he had a good deal of pain in the head, and one day, feeling strangely, he arose to go to the window, when his wife observed a spasm over his right cheek and neck. It was a twitching, and did not involve the arm. Consciousness was not lost. A similar attack occurred the next year, and again one the third year, this time taking place at night. The wife was certain that no spasmodic movement took place in the hand or arm before 1885.

The first spasm, as the first indication of cerebral disease, was particularly interesting. It was the only symptom in this case for three years. It was confined to the right cheek, and perhaps the side of the neck. Two years ago the symptoms became more marked. On one day he became unconscious, fell, and bit his tongue, having probably a convulsion. He had had similar attacks at long intervals since. These epileptic attacks were preceded by an aura. Then there took place twitching and jerking in the right side of the face, right hand and arm, and loss of consciousness. They occurred at all hours. No exciting cause had been observed. The speech had become thick. The general health was good.

Dr. Seguin first saw the patient on August 26th. He stated that the attacks always began in the right facial muscle; the spasms in the hand were always secondary to those in the face. He was awkward in the use of the right hand. He felt a numb sensation in the right arm. The speech was thick. The eyes were normal in every respect. He stood equally well on either foot. The patellar reflex was greater on the right side. There was slight diminution of tactile sensation over the right cheek. Intermittent fever had reappeared. The diagnosis was that of a tumor in the left motor zone involving the facial centre. He saw the patient again, September 21st. He had had only one severe epileptiform attack since August 21st. The speech had become worse, being slow and somewhat interrupted. The patient could not always think of the right word either in speaking or writing. The movement in writing was also interfered with. The tongue was tremulous, but projected nearly straight. The paresis of the right arm was more pronounced. The muscular sense was normal. The other symptoms remained about as before. The desirability and feasibility of an operation were discussed. Whether the tumor was cortical or subcortical was a question of doubt. There was at this time no local pain in the head, which was characteristic of a tumor in many cases.

The patient was examined again on October 19th. He had had a convulsion on the 15th without loss of consciousness, the attack lasting eight minutes, or twice as long as usual. At this visit the mouth deviated to the left in whistling, the tongue protruded slightly to the right, the saliva escaped from the right buccal angle. With the eyes closed a silk handkerchief dropped from the right hand, because of diminished muscular sense. There was decided tenderness on percussion over the motor zone of the left hemisphere. An exploratory operation was advised. Iodide of potassium had been thoroughly tried, but without effect. Between this date and that of the operation, November 17th, the patient had several partial attacks; he suffered much from headache, localized principally on the left side in the motor region. The motor symptoms due to the cerebral lesion increased.

The patient entered the New York Hospital as a private patient of Dr. Weir, and was operated upon November 17, 1887. Twice before the operation the temperature was carefully tested at different points over the scalp, but the result was practically negative. While the symptoms were suggestive of a cortical lesion, there were certain facts in the history of the case which prepared them to find a subcortical tumor.

DR. WEIR described the details of the operation, which was carried out under antiseptic conditions, no spray, however, being used. The head was shaved the previous day. A minute perforation was first made through the scalp at the point previously indicated by Dr. Seguin, corresponding to near the centre for the face. Through this perforation a mark was made on the skull with a sharp pencil to indicate the place to be centred by the trephine. An oval flap, including the periosteum, three inches broad, was raised and turned back toward the forehead. Many bleeding points were secured. Two openings were made with the trephine, and they were then joined, making the cranial opening three inches by two. The dura mater bulged only slightly and presented a normal appearance. One vessel of the pia was wounded, and ligated with some difficulty. Nothing abnormal was seen on the surface of the brain. The finger recognized no tumor until firm pressure was made posteriorly, when it encountered deep resistance from a mass of small size underneath the previously suspected convolution. It was not incapsulated, and was readily lifted out by the Volkmann spoon previously blunted for the purpose. A piece of brain-matter about the size of a pea was removed. The finger could be passed in about an inch and a half to the bottom of the cavity from which the mass had been removed. No hemorrhage took place from the brain itself.

A rubber drainage-tube was carried to the bottom of the cavity and out through the posterior margin of the wound. The dura was stitched together except over the small area where the tube emerged. A final washing of the wound with a solution of corrosive sublimate, 1 to 5,000, was made. The disks of bone were replaced, having been kept warm and guarded antiseptically.

At the termination of the operation the pulse was 125; the general condition was good. The tumor, which was of the size of an almond, was pronounced by Dr. Peabody to be an infiltrating sarcoma. It lay a little more than an inch below the surface of the brain, and its anterior edge about touched the anterior edge of the precentral lobe.

Three or four hours after the operation, when the patient had come from under the influence of the ether, he could move his right leg and arm apparently as well as before the operation; his facial paralysis was somewhat more marked. He was slightly aphasic. The temperature reached 102° F., but subsided, and the patient was allowed to return home a month after the operation.

DR. SEGUIN gave the further history of the case. He had grave doubts whether the tumor was purely medullary. It was possible the deep sulcus between the second and third frontal gyri was involved in the growth. On December 8th the patient was again examined carefully. There had been no convulsions since the operation. Most of the symptoms which were present before the operation were elicited. There was, however, no escape of saliva. A new symptom was that the left pupil was a little larger than the right. There was no tremor of the upper extremities, and the grasp of the right hand was fully as strong as before the operation. The knee-jerk was equal on both sides. Pricking was more acutely felt on the left fingers than on the right. The speech was slightly thick, and the patient hesitated occasionally for a word. December 10th, the patient had a convulsion which began in the right face, extended over the right side, and then became general. He had another on the 16th. On the 17th he was allowed to return to his home in Bridgeport. The symptoms due to the cerebral difficulty were aggravated during the winter by recurrence of intermittent fever with jaundice. The strength of the muscles of the right arm was two-thirds that of the left. Dr. Seguin thought the convulsive attacks would have been relatively infrequent had it not been for the fever. There was apparently no greater loss of sensibility on the right side than formerly. In April the grasp of the right hand was estimated to be about half as strong as that of the left. The patient said he no longer felt numbness in the right hand. The muscular sense was practically perfect. His wife declared that the muscular twitching in the right face had ceased.

Dr. Seguin thought the results, four and a half months after the operation, showed that life had been prolonged. It was not improbable the patient would ere this have died of coma, if not a sudden death, had the operation not been done, for the symptoms had been rapidly progressing the last month prior to removal of the tumor.

He would be unwilling to estimate the damage done to the speech-centre and the effect upon other portions of the brain since the operation, until after the malarial fever from which the patient had been suffering had entirely subsided. The mental condition showed that there was no increased intra-cranial pressure. So far there was no evidence of further growth of the disease.

This case was of great interest in connection with recent progress in the physiology of the brain, and the application of such physiological knowledge to surgical interference.

The symptoms pointing to the development of a tumor in the brain could now be recognized by any physician with a fair degree of ease. Having made the diagnosis of a tumor, it would be further necessary to decide as to the propriety of operating. This would depend upon several conditions; for instance, the location of the tumor, whether it was or was not single, and what was its nature. Dr. Seguin here gave the topography of the brain as based on its physiology, determined by physiological experimentation and clinically acquired knowledge. The symptoms produced by tumors in the motor and sensory zones, and according to whether they were cortical or subcortical, were given as far as our present knowledge enabled us to recognize them. The early limited spasm or paresis he had long looked upon as an important guide to correct localization. He proposed to call it the "signal symptom" of cerebral tumor.

A tumor situated in the sensory zone for sight, for half vision, either upon its external aspect, or the mesial, or inner aspect of the occipital lobe, or within the occipital lobe, was one of the most easy to diagnosticate.

Regarding the significance of headache and the scalp-temperature in distinguishing between cortical and subcortical tumors, Dr. Seguin's conclusion was negative. The surgeon would be influenced in his decision regarding the propriety of operating, by the probability of the tumor being multiple, also by its probable character. It seemed to him undesirable to operate in cases in which tuberculosis was evident, or in which there was a cancerous tumor in some other part of the body besides the brain. As to diagnosis of strictly primary tumor of the brain, whether tubercular, sarcomatous, gliomatous, etc., it was always extremely problematical, and based upon guess rather than symptoms.

Dr. Weir then read a part of his paper giving the surgical history of tumors of the brain. He began with the case of Bennett and Godlee, reported in the *Lancet* of 1884, and continued with those of Victor (Hostley?), Bennett, Keen, and the early one of Torenta. He then gave place to

Dr. Keen, of Philadelphia, who gave a condensed report of a case of tumor of the brain operated upon by him, December 15, 1887. The patient, at the age of three years, fell from a window, and struck the head upon a brick. No symptoms developed until twenty years after the wound had been inflicted. He then began to have epileptic attacks. There was no history of a signal symptom alluded to by Dr. Seguin. There developed paralysis of the right leg, arm, and face, and aphasia, all of which pointed to tumor of the left side of the brain. There was also certain trouble in the right retina, which was attributed after the operation, rather than before, to ear disease, and basilar meningitis, the result of the ear disease. There was also deviation of the head to the right. Recovery from paralysis of the right leg, face, and arm, and from the aphasia was complete. The symptoms left him in much doubt as to the nature of the trouble, and as to the size of the tumor, if tumor it was. The operation was much like that performed by Dr. Weir. The opening in the skull was nearly three inches by two. There was much hemorrhage, which was controlled partly by hot water, partly by pressure, and partly by ligature. The vessels were very brittle. The tumor displaced two ounces and a half of water, and was situated in the motor centres for the right face, arm, and leg.

The next day pressure symptoms were very marked, causing paralysis of the right arm, face, and leg. These symptoms increased for two days, when he removed the dressing and found a clot of not less than four ounces. The patient had recently recovered from cerebral hernia. Dr. Keen said he expected soon to report the case in full.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, March 5, 1888.

C. L. Dana, M.D., President, in the Chair.

Dr. Dana presented the report of a case (see p. 433) of

THOMSEN'S DISEASE.

Dr. G. W. Jacoby had examined the specimens and compared them with the specimens from his own case. He did not consider this the typical case which Erb's monograph had described. Erb had excluded all of the published cases but eight. Erb's typical case showed no disease of the central nervous system. In Dr. Dana's case there was at least a suspicion of such disease. The reactions of the muscles, too, were incomplete or failed to comply with the requirements as given by Erb. The speaker did not, however, believe in Erb's lines. He thought they were too close. While this case did not come under the heading as limited by Erb, it did come under the name as understood by others. Erb's theory was that of a disorder of the muscles themselves, a congenital malformation of the muscular system. If the fissuring of the muscles and the increase of nuclei in the case under discussion were dependent upon a central affection, this alone was an interesting fact. It would demonstrate that, microscopically alone, a diagnosis of myomotonia congenita could not be made. Our knowledge of primary muscle affections was not yet on a solid basis. It was possible that there was first trouble in the central nervous system, from which the other proceeds.

Dr. Heitzman had examined the specimens with a low power, and had been impressed with the belief that this was not a genuine case of Thomsen's disease. In the typical case the nuclei of the muscles were augmented. The reader of the paper had made Erb's mistake when he spoke of the nuclei of the sarcolemma. The sarcolemma was a structureless membrane. There was also augmentation of the sarcoplasts or muscular corpuscles. There was too much muscle-substance from the earliest period. Hence the name myomotonia congenita. Dr. Dana's case, on the contrary, could not be called congenital, as the disease had not developed until the twentieth year. Second, the muscle-fibres were not distinctly augmented in size. If compared with those in Dr. Jacoby's case, the difference was marked. Third, the fissuring was not prominent. For these three reasons he was loath to accept the diagnosis. He was, on the other hand, unable to tell what else the condition could be.

Dr. Emerson had examined the eyes. There was no insufficiency of the muscles, and the pupils had reacted all right.

Dr. Starr realized that we could not yet lay down any positive deductions in regard to electrical reactions. In degeneration we got the pure reaction of degeneration, an intermediate reaction of degeneration, and the normal muscle-reaction. Erb had given the reactions for three cases only. Other cases might not substantiate their results. He considered Dr. Dana's case valuable and one to be put on record. For reliable data, a large number of cases were required. Even Dr. Heitzman's objection of muscular anomalies was not fatal to the theory of its being a case of Thomsen's disease.

Dr. Dana explained that he had not called the case one of myomotonia congenita, but an atypical case of Thomsen's disease. It remained to be proved whether myomotonia was always congenital. He had recently seen a case which commenced at the eighth or tenth year. Since Erb's book, four additional cases had been reported besides his. He agreed with Dr. Heitzman, that the enlargement of the fibres was not positive. He had, with a stage micrometer, measured the fibres in the specimen from Dr. Jacoby's case, in that from the case under discussion, and in that from his own arm. He had found the fibres in the first, $\frac{1}{400}$ to $\frac{1}{300}$ of an inch broad ; in the second, $\frac{1}{250}$ to $\frac{1}{400}$; and in his own, $\frac{1}{450}$ inch. Thus, in the case under discussion, some of the fibres were larger and some smaller than the normal. The increase of the nuclei, however, was in some of the specimens shown typically, as in Erb's plate. He thought that the fissuring might have been produced artificially by tearing. Electrically there was greatly increased irritability of the muscles both to galvanism and faradism. The contractions were tonic, with closure tetanus. There was normal excitability of the nerves. Clinically the patient presented the phenomena of Thomsen's disease. It remained to be proved whether the phenomena of Thomsen's disease could be produced by disorders in which the central nervous system was involved.

Dr. Starr presented a specimen of

TUMOR OF THE BRAIN.

The patient was a woman, at the time of death fifty-six years of age, who for two years had presented the general symptoms of tumor of the brain, vertigo, projectile vomiting, dulness of the mental faculties, and optic neuritis. During the last five months she had been carefully examined, but without obtaining any evidence which would locate the tumor, if one occasion were excepted, when, during an attack of vertigo, she fell forward and to the right. This was not a permanent symptom, and was the only evidence pointing to cerebellar disease. The tumor was of the size of a hen's egg. It was found on the under surface of the tentorium, simply resting upon and compressing one lobe of the cerebellum. There were no adhesions, and it was unfortunate that no symptoms had pointed to its location, as it might have been easily removed. In 1878 Nothnagel had remarked that tumors of the lateral lobes of the cerebellum did not give rise to the symptoms of inco-ordination common to other cerebellar tumors.

Dr. J. West Roosevelt presented the report of a case of

BASEDOW'S DISEASE, WITH AUTOPSY.

The case was one of negative interest. The patient had been admitted to the wards of Roosevelt Hospital, May 25, 1887. The patient was a female, widowed, forty-seven years of age, a house-keeper. Both the personal and family history was good. Two years before admission the patient had commenced to complain of palpitation, dyspnœa upon exertion, and swelling of the throat, which was largest upon the right side. The patient could not lie upon the right side. In the course of a year the eyes commenced to protrude, and at the time of entering the hospital she had a profuse watery diarrhœa.

The pupils were found to be equal, the reaction to light and accommodation good. The lids did not follow the eyeballs. The neck measured thirteen inches around the lower thyroid region, and ten and one-half inches around the upper thyroid region. There was no dysphagia to solid food. The pulse was 100 to 120, and the respiration 38. The apex-beat was found in the fifth space, mammary line. There was epigastric pulsation, and the area of dulness was slightly increased. There was a short systolic murmur at the apex. There was a systolic thrill over the jugulars, and a continuous venous hum. The pulmonary resonance was exaggerated. The veins of the retina pulsated ; the arteries did not. There was no tremor. The patient lived until May 31st. She suffered from watery diarrhœa and restlessness, but was not otherwise sick. In walking to the bath-room one evening she fell dead on the floor. Autopsy showed the thyroid reduced in size, but still moderately enlarged, and of a pink color. The kidneys showed a trace of fibrous tissue, but otherwise the organs were normal. There was apparently nothing abnormal in the medulla, nor in the sympathetic or vagus nerves. Microscopic examination of these parts also showed nothing.

Dr. W. O. Moore had seen twelve cases, all females, average age forty years—the youngest thirty-one and the oldest forty-five years. Ophthalmic examination had showed simply enlargement and tortuosity of the blood-vessels. Great relaxation of the bowels had been present in one of the cases, having as many as ten evacuations in the day, which it was impossible to control. Electricity had been of no avail in these cases. All had presented the three characteristic symptoms—exophthalmos, thyroid enlargement, and rapid heart-action. All had the symptom to which Von Graefe first called attention, namely, a disturbance of the usual co-ordination of the movements of the eyeball and the upper lid, so that when the patient looks downward below the horizontal meridian the lid no longer follows the eyeball in its motion, but halts in its course. This fault in the action of the lid was supposed to be due to some defect in the orbicularis, and was not present in cases having prominent eyes from other causes. Occasionally the prominence was so great as to cause the eye to be exposed at all times, both when waking and asleep. In one case in his expeience suppuration had occurred and the eye had been lost. A history of the case was given.

Had it been seen earlier the writer would have united the upper and lower lids, thus covering the eyeball. At the end of a few weeks the lids would have been reopened, when, as a rule, the exophthalmos would be found improved and the corneal trouble removed. For constitutional treatment the patient should receive digitalis, ergot, and tonics. This case was remarkable from the fact that an eye was lost by suppuration, and that this loss was associated with phthisis in the other eye. The loss of an eye from exposure was so rare that the writer knew of but ten reported cases in this country, while Wells reports only one case.

Dr. Starr had been interested in the report of Dr. Roosevelt's case. The fact that no lesion had been found in the sympathetic in this case did not, of course, prove anything conclusive. Ross had reported eight cases in which such lesion had been found out of twelve cases as far back as 1832. The pathology, however, was not clear. It was difficult to understand how any one lesion could produce all of the phenomena of this disease. The hypothesis accepted by Gowers was that of lesion of the vagus nucleus in the medulla. The rapid pulse would be accounted for by the loss of the inhibitory power of the vagus. It was known, too, that vaso-motor disturbances were produced by irritation of the medulla in this region. The speaker had, some time ago, collected twenty-one cases of lesion of the medulla, in eight of which the lesion was in its upper part, in the region of the nucleus of the tenth nerve. In all of these cases there were subjective flushings and objective increase of perspiration; while in the thirteen in which the lesion was in the lower part of the medulla there were no vaso-motor symptoms whatever, thus substantiating the hypothesis of the physiologists that there is a vaso-motor centre in the medulla, and that this centre is in the neighborhood of the nucleus of the tenth nerve.

The speaker had personally observed seven cases, five in the female and two in the male. In all but one palpitation of the heart had been the first symptom. This disproved the theory that the goitre was primary, and that the other symptoms were due to the pressure of the tumor upon the pneumogastric nerve. The pulse had ranged between 90 and 155. In all but one the eyes had been prominent. In six there had been nerve-symptoms; in four, tremors; in four, Von Graefe's symptoms; in six, flushes. Mental disturbance had been present in one case, in which there had been delirium every night for several months, and subacute mania for several weeks. The first symptom in this case had been insomnia, which resisted treatment. The reader supposed it to have had its origin in a condition of the vessels of the brain, similar to that in the back of the eye and the thyroid gland. Digitalis had done no good in his experience. Ergot and bromide had quieted the tremor, but no drug which he had tried had reduced the heart. He had used electricity, according to Benedict's recommendation, but without result. He had never been able to obtain any retardation of the pulse.

Dr. Rockwell had met about thirty cases of this disease, and in nine cases he had obtained an approximate cure. He had employed diet, galvanism, and very full doses of digitalis, bromide of zinc, ergot, and iron. He had authentic records of his results. He believed that the cases not benefited by treatment were organic, and that those benefited were functional in origin. Those having all of the cardinal symptoms were more often responsive to treatment than those in which the symptoms were more incomplete. He recalled a case in which there was a pulse of 110 reduced to 30. There was puffiness of the eyelids in this case. In the galvanic application one pole had been placed over the eyelid, and the other behind the sterno-cleido-mastoid muscle at its upper third. In another case, presenting the three symptoms for several years, the pulse had ranged from 130 to 150. There was dilatation of both pupils, and a pulsating swelling over the solar plexus. This patient was placed upon a milk diet, and persistently treated for many months, when the pulse had fallen to below 100, and the swelling of the thyroid and the exophthalmos had become less.

Dr. Starr asked whether Dr. Rockwell had obtained reduction of the number of the heart-beats while the current was being used; also whether he had ever obtained paling of the face and dilatation of the pupils—phenomena which follow galvanization of the sympathetic when needles are used.

Dr. Rockwell replied that he had not made his observations during the application, but that subsequently such slowing had been demonstrated. Lowering of the pulse was also a very common result of general faradization.

Dr. George W. Jacoby considered exophthalmic goitre a rare disease. For eight or nine years he had seen in his dispensary from six hundred to seven hundred neurological cases a year. Not more than a dozen of these had been cases of exophthalmic goitre. The patients had been regular in attendance, and treatment had been persistent, but he had tried every means heralded without result. Subaural galvanizations had been without effect upon the color or the pulse. He considered the disease a hopeless condition. Bodily and mental rest furnished about all which could be done. He had tried faradism, according to the recommendation of Vigouroux, but also without result.

He thought the exophthalmos the least constant symptom. Where goitre was present one side of the neck was usually larger than the other. Some said that the right was always the larger. This he could contradict, as in a case which he had recently seen with Dr. Birdsall the enlargement had been equal upon both sides. Von Graefe's symptom was not always present. Tremor was often the first symptom. In one case in his experience tremor had existed for a year before the development of the other symptoms. At the end of the second year these had become well developed and bronzing of the skin also was present.

ELECTRICAL RESISTANCE.

Vigouroux had stated that the electrical resistance was diminished in all cases, and even in the commencement of the disease. This, if true, would be an important diagnostic point. In twenty cases published by Wolfenden this lowered electrical resistance was present. Two of these cases are published in full. In one of the latter the resistance was only 300 ohms. It was mentioned that there was profuse sweating in this case. In the second the resistance was 200 ohms. Of this case it was said that there was clamminess of the surface and sweating. In the other eighteen cases the resistance was from 500 to 1,300 ohms. The speaker said that the standard of resistance, however, varied according to the method used. It had been given as high as 300,000 to 400,000 ohms, by Jolly. Gärtner gave it as 30,000 to 40,000 and here we estimated it at one-third or one-fourth that. He had recently tested the resistance in three cases, his method having been to place the body in the circuit, the electrodes being equal in size, and wet. When the galvanometer ceased being deflected the body was taken out of the circuit, and the resistance coil inserted until the deflection of the needle was again brought to the same point. The amount required equalled the resistance of the body. Comparative observations were at the same time taken upon himself. The first case was that of a female, twenty-eight years of age, with exophthalmos, palpitation, and sweats. The resistances obtained were as follows:

Through the palms, patient	6,000 ohms.
Self	8,000 "
Through the goitre, patient	1,200 "
Self	2,400 "
Through the posterior part of the neck, patient	1,400 "
Self	2,400 "

The second case, a patient of Dr. Birdsall, presented goitre, with palpitations and exophthalmos, and the comparative observations were taken upon Dr. Birdsall and himself. The resistances obtained were as follows:

Patient, through the hands	5,000 ohms.
" " goitre	800 "
" " the posterior part of the neck	1,000 "

The measurements in his own case were respectively 5,500, 2,400, and 2,000 ohms; and in Dr. Birdsall's case, 8,000, 1,000, and 1,000 ohms.

The third case:

Patient, through hand	5,000 ohms.
" " goitre	1,000 "
" " neck, antero-post.	1,500 "

Control subjects (two):

Hands	11,000	and	10,000
Thyroid	4,000	"	3,000
Neck	3,000	"	3,000

The reduction was thus scarcely one-fourth, certainly not one-half, and not more than would be accounted for by the maceration of the skin, due to the abundant perspiration in these cases, or, as in the goitre, to the fluxion of blood. The speaker failed to see how any importance could be attached to the test as a symptom.

Dr. Dana was surprised to hear that there was any dispute in regard to the possibility of lowering the pulse by galvanism. In a recent case of Basedow's disease, in Bellevue Hospital, a pulse of 140 had been found regularly lowered fifteen or twenty beats after the current had been applied. The fact was admitted in Gower's recent work. The sedative effect of galvanism was generally admitted, though we could not say whether it was produced through the pneumogastric or the sympathetic nerve. Dr. Gower's theory of the disease he thought hardly satisfactory. Lesion of the nucleus of the pneumogastric should give the same symptoms as division of its trunk, and this never gave rise to the phenomena of Basedow's disease. It might, perhaps, be said that this disease was due to lesion of the nucleus of the pneumogastric and neighboring parts. The speaker had tested the electrical resistance in two cases; in one it was diminished slightly, being about 1,200 ohms. In testing he placed one electrode in the region of the seventh vertebra, and the other on the sternum. His method was to determine the electro-motive force of the cells, then to estimate the resistance by the ohm formula. He had made a number of examinations of patients. He had found electrical resistance lessened in tachycardia.

Dr. Roosevelt had had the same experiments as Drs. Starr and Jacoby. He had used both strong currents and weak currents without any influence on the sympathetic nerve. He was surprised to hear digitalis recommended. He believed that digitalis was without value for heart failure, except from organic disease. He had had five cases of exophthalmic goitre under observation. Two of these had improved, but both were cases of young anæmic girls. The measurement of electric resistance he thought a difficult problem because the factors varied.

A New Method of Testing the Refraction of the Eye.—Mr. A. Legge Roe describes (*The Lancet*) the following simple method of testing refraction: A trial frame is applied in the usual way, one eye excluded with a diaphragm, and the patient instructed to look steadily at a distant object. A blackened disk, perforated in the centre with a hole two millimetres in diameter, is rapidly passed across the eye to be tested in a horizontal direction by the surgeon. The patient is questioned as to the direction taken by the object; if the motion is in the same direction as that of the disk, myopia is present; if in the opposite direction, hypermetropia; if there is no apparent motion, emmetropia. The vertical meridian is then tested in the same way. If the motion is in opposite directions in the vertical and horizontal meridians, mixed astigmatism is at once diagnosed. An error of refraction having been detected, suitable lenses are gradually added and the disk used as before, until there is no apparent motion of the object. The defect will then be corrected. There is a tendency to overestimate myopia about .5 D., and to underestimate hypermetropia .75 D. A good test-object is a small picture-frame, using the vertical sides for testing the horizontal meridian, and *vice versa*. The explanation of the above phenomena will be found in Scheiner's test, of which this is apparently a modification applied to refraction.

Chins.—A long chin declareth a man to be peaceable, yet a babbler. They that have little chins are much to be avoided and taken heed of, for they are full of impiety and wickedness, and are spies like unto serpents. If the end of the chin be round, it is a sign of nice manners. But the chin of a real man should be square.

Correspondence.

SHALL A SURGICAL INVENTION BE PATENTED?

To the Editor of The Medical Record.

Sir: The Code of the American Medical Association says: "Equally derogatory to professional character is it for a physician to hold a patent for any surgical instrument."

The Code of the Medical Society of the State of New York says: "It is equally derogatory to professional character, and opposed to the interests of the profession, for a physician to hold a patent for any surgical instrument." Both codes are at fault. It is not derogatory to professional character, nor opposed to the interests of the profession, for a physician to hold a patent for a surgical instrument. But it is derogatory to the *character of the profession*, and opposed to the advancement of science, and to the interests of society at large, for these statements to exist in these codes.

Professional character means the unity and exemplification of all those excellent qualities, or principles, which, controlling the uniform life of a physician, tend to promote the highest physical and moral good of his fellowmen. These qualities are: Benevolence, beneficence, liberality, honor, truth, justice, equity, industry, temperance, self-denial, self-respect. The lustre of none of these qualities is dimmed in a physician by his holding a patent for a surgical instrument; but each one of them is exalted thereby, in direct proportion to the value of the instrument to mankind.

The *character of the profession* is pre-eminently in the keeping of those organizations which undertake to lay down rules for the conduct of individual physicians. The chief elements or principles which go to make up the character of the profession are: Justice, equity, truth, and wisdom. Not one of these qualities but suffers loss by the existence of these kindred statements in our medical codes.

It remains to be seen which of the two organizations, the American Medical Association or the Medical Society of the State of New York, will be the first to see and rectify this mistake.

Elmira, April 5, 1888.

THE FLESH-BRUSH A REMEDY FOR "WINTER ITCH."

To the Editor of The Medical Record.

Sir: The writers on "Winter Itch," whose letters of appeal in The Medical Record have been read by me, may be glad to know that, although I am not a dermatologist, I have met the disorder referred to, and have conquered it with a hair brush. I have thought that the trouble arose from the temperature-changes experienced in removal of clothing, cooling down after walking, etc., producing an irregular contraction of the various elements composing the skin's structure, and thus disturbing the regular distribution of the circulation. In the case above mentioned a thorough, hard scrubbing of the itching surfaces with a dry hair brush of moderate stiffness of bristle, every morning and evening, gave immediate relief to the itching, prevented excoriations, and the annoyance gradually disappeared. Internal and external medication, baths, etc., did no good whatever.

168 West Fifty-eighth Street.

The Marriage Vow.—Three centuries ago the woman also promised, "to be buxom to thee till death us depart or separate."

New Instruments.

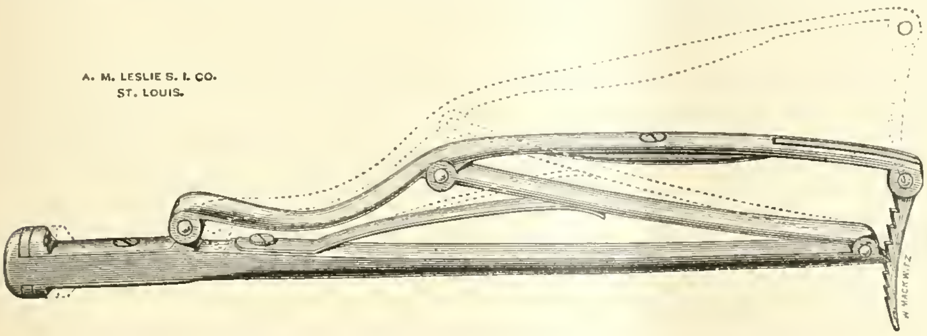
A NEW NEEDLE-HOLDER (POCKET-CASE) FOR FLAT NEEDLES.

By A. H. MEISENBACH, M.D.,

CONSULTING SURGEON TO THE CITY HOSPITAL, ST. LOUIS, MO.

It has been sought to supply in this needle-holder an instrument with which the flat needles of Hagadorn can be effectually used, and which is at the same time small enough to carry in the pocket-case. The Hagadorn needle-holder now in use is too bulky to carry, except in the operating bag, and, therefore, the flat needles have not been a feature of the pocket-case.

The superiority of the flat needle over the ordinary surgical needle is in its sharp cutting point, which facilitates the rapidity of penetration, and makes an incision at right angles to the wound, so that when traction is made on the suture the needle-wound closes, while with the ordinary surgical needle the incision made by the needle is parallel with the wound, and when traction is made on the suture the needle-wound gapes. Another very important feature of the flat needle is its large eye, which adapts it to the use of catgut for suturing, which with the ordinary surgical needle is very difficult or impossible.



Cut, Full Size.

The mechanism of the needle-holder is readily seen in the accompanying illustration. It is five inches long, and when closed (as shown in cut) is less than three-fourths of an inch wide. All of its parts are very strong, and its range of adaptability is such that it will hold firmly the largest, as well as the smallest, flat needles. It will also hold round needles very effectually.

The general form of the needle-holder is such that it is very easy to manipulate. The jaws are copper-lined, and so arranged as to grasp the needle on three sides, the advantage of which readily suggests itself to the operator.

Strychnine as a Hypnotic.—Dr. Lauder Brunton has employed strychnine in insomnia from "over-tiredness" with very happy effects. He says that it occurred to him that as strychnine is one of the most powerful stimulants, if not the most powerful nervous stimulant, that we possess, a small dose of it might have the effect of bringing the depressed nervous system up from the condition of over-fatigue to that of simple fatigue, and thus inducing sleep. He found that it acted exactly in the manner that he had expected, and induced comfortable, healthy sleep without any disagreeable effects next day. The way in which he has used it has generally been either in the form of the tincture of nux vomica in doses of five to ten minims, or in the form of granules, containing $\frac{1}{200}$ of a grain of sulphate of strychnine in each. One, two, or more of these granules were given at bed-time, and the dose was repeated if the patient happened to awake within one or two hours afterward. Dr. Brunton thinks it very doubtful whether strychnine would answer in other cases of sleeplessness than those arising from overwork or worry, and more especially from overwork.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 8 to April 14, 1888.

Bushnell, George E., Captain and Assistant Surgeon, from Fort Preble, Me., to Camp Pilot Butte, Wyo. S. O. 79, A. G. O., April 6, 1888.

Stephenson, William, First Lieutenant and Assistant Surgeon, from Camp Pilot Butte, Wyo., to Fort Verde, Ariz. S. O. 79, A. G. O., April 6, 1888.

Mearns, E. A., First Lieutenant and Assistant Surgeon, from Fort Verde, Ariz., to Fort Snelling, Minn. S. O. 79, A. G. O., April 6, 1888.

Knudler, William L., First Lieutenant and Assistant Surgeon, from Fort Snelling, Minn., to West Point, N. Y. S. O. 79, A. G. O., April 6, 1888.

Borden, W. C., First Lieutenant and Assistant Surgeon, from Fort Douglas, U. T., to San Antonio, Tex. S. O. 79, A. G. O., April 6, 1888.

Edie, G. L., First Lieutenant and Assistant Surgeon, from San Antonio, Tex., to Fort Douglas, U. T. S. O. 79, A. G. O., April 6, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 14, 1888.

Percy, Henry T., Passed Assistant Surgeon, from Naval Academy, and to Hospital, Washington, D. C.

Crawford, M. H., Passed Assistant Surgeon, from Hospital, Washington, D. C., and wait orders.

Flint, J. M., Surgeon, from Fish Commission duty, and special duty at Smithsonian Institution.

Parsons, R. C., Surgeon, to duty in charge of Army and Navy Hospital, Hot Springs, Ark.

Stone, E. P., Assistant Surgeon, from further treatment, and to duty, Hospital, New York.

Kindleberger, David, Medical Director, from Hospital, Washington, D. C., and wait orders.

Hoehling, A. H., Medical Inspector, to Naval Hospital, Washington, D. C.

Harmon, G. E. H., Passed Assistant Surgeon, to duty, Naval Academy, Annapolis, Md.

Solvine.—Solvine is a whitish, opalescent substance prepared by the action of sulphuric acid upon oil of almonds or castor-oil. It acquires its peculiar name because it has a remarkable solvent power upon a number of comparatively insoluble substances, such as iodoform, naphthalin, naphthol, salicylic acid, cantharidin, santonin, aloin, etc. It is miscible in all proportions with glycerine, and with substances dissolved in glycerine. It forms clear mixtures with ether, chloroform, benzole, turpentine, and essential oils; and these mixtures are themselves soluble in water, if there be no great excess of any one ingredient. These facts have led to a recommendation that solvine shall be used as an excipient for a variety of medicaments intended for endermic use, instead of lard, vaseline, lanolin, and so on. According to the *Medical and Surgical Reporter*, there is theoretically some danger of toxic action from its ready absorption by the skin.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 14, 1888:

	Cases.	Deaths.
Typhus fever	2	0
Typhoid fever	6	5
Scarlet fever	153	30
Cerebro-spinal meningitis	5	5
Measles	29	4
Diphtheria	158	31
Small-pox	21	3
Yellow fever	0	0
Cholera	0	0

THE PHYSIOLOGY OF MEMORY.—To those who have the time and the taste for recondite studies, the investigation of that wonderful faculty which enables us to recall past events, and project them once again on to the field of consciousness, possesses a peculiar interest of its own. It is not given to everybody to be able to analyze their own sensations, much less those of other people, and the ability to trace the links of the mysterious and delicate mechanism can only be acquired by long practice of close and constant observation. The first step is to clearly understand that we are dealing with a mechanico-vital process precisely of the kind which we recognize in other and more accessible organs. All we know of these processes at present is that function means molecular change, and hence every thought that passes through the mind, every sensation we experience, every act we do, produces some definite change in our bodily structure. The change, moreover, is permanent, and leaves its trace just as every variation of facial expression leaves its imperceptible but cumulative impress on the features. A proper understanding, so far as our knowledge will permit, of the mechanism of the memory, is not a vain scholastic pursuit, since from it we can derive valuable information bearing on the use and training of that very important faculty, the want of which hampers education and leads to a waste of intellectual energy. We find on reflection that the mental processes are capable of the same training and derive the same advantage from it as muscles do. Just as there are certain movements which are performed with difficulty for the first time, but become easier by repetition, so certain mental efforts can only be satisfactorily accomplished after practice. The trained sense is capable of apprehending what to the untrained sense is imperceptible, owing to the greater aptitude of the sense organ through training. The effects of training become part of us, and influence our will to a degree which many would *à priori* be disinclined to allow. A man cannot at will change his gait, his handwriting, his voice, nor even his modes of thought, simply because the parts concerned have developed in the direction in which they have been exercised, and cannot readily act otherwise. As life is one long training, so its influence becomes more marked as age advances, and as he gets older a man becomes less and less able to strike out new lines of thought and conduct. According to Mr. Kay, whatever parts are concerned in the production of a sensation or in effecting a movement, are necessary to a full and complete recollection of it. Thus the senses are not only necessary for the receiving of impressions, but are, also concerned in the recollection of them. Physiologists assert that the brain alone is the seat of the memory, but, as Professor Bain says, "the organ of the mind is not the brain by itself; it is the brain, nerves, muscles, organs of sense, and viscera." The importance of this doctrine is that it enables us to explain how the mind can communicate with the organs of sense or the muscles in recalling past sensations. If we close our eyes and think intently on a certain color, the retina becomes exhausted for the reception of that color exactly as if we had been actually gazing upon it and in about the same space of time. As Mr. Kay says, the artist who can recall to mind a scene he has once looked upon so vividly that he can paint it from memory, as if it were actually before his eyes, must be supposed to have the power of again projecting on the retina the impression previously made on it. There is an essential difference between sensation and perception. In the former an impression is conveyed to the brain and awakens consciousness, and in the latter the conscious brain examines and reports on the sensation and localizes it. The bearing of these arguments is that, since memory is not the brain alone, but also the organ of sense, the proper training of the senses is an essential factor in the cultivation of memory. They must be trained, first to observe, and secondly to reproduce—two sets of faculties which are quite distinct from each other, one depending on attention, the other on association. Attention is the power of concentrating the mind upon a given subject; association consists in bringing together the ideas that most resemble each other and which we wish to reproduce together. Although every thought and act leaves its physical impress on our tissues which is never obliterated, they may never come up consciously before the mind, though their presence gives a color or bias to all our after-thoughts and feelings. It is the permanence of what we may call the receptive faculty which justifies the hope that, by the employment of a better method of perceiving and associating impressions, the reproductive powers of memory may be trained to a far higher standard of usefulness than is usually attained.—*The Medical Press.*

EPITHELIOMA TREATED BY CHLORATE OF POTASH.—Dr. Hyvernaud has treated 63 cases of epithelioma by local applications of chlorate of potash; of these, 32 were cured, 15 were benefited, and 16 cases were unrelieved. In the successful cases the disease was situated on the skin of the face, nose, eyelids, cheeks, neck, in the lumbar region, on the back of the hand, and on the inner surface of the leg. Chlorate of potash fails, as a rule, when the mucous membrane is the seat of disease, although two cases of epithelioma of the lips and nostril were cured by it. It is especially useful when the affection is slow in its progress. A six per cent. solution slightly heated, or a fine powder of chlorate of potash, is applied to the wound, after it has been freed from scabs. The dressing is renewed once a day or oftener. The effect of the solution is chiefly to heal the wound, while the powder slightly cauterizes it. The surface of the tumor or ulcer is thus destroyed, small eschars come away, and cicatrization ensues. In most cases several weeks, or even months, are required to obtain complete cicatrization.

HINTS BEARING ON FEES.—Always make a charge for each service. This gives it a business value in the eyes of the patient.

The charge should always be just and reasonable; then no deduction is necessary.

Insist always upon full payment, based, if necessary, upon itemized accounts.

When the patient asks for a reduction of his bill, recall the sacrifice of sleep, of meals, and of comfort in rendering him prompt service. Think of your preferences then and of his now.

Never allow sentiment to interfere with business. The "thank you" is best emphasized by the silvery accent of chinking coin.

The loss of money by sickness only affects one side, in every other business. Why should it be different when the doctor is to be paid?

Always charge a fixed fee, and never trust to his generosity or embarrass him by guessing an amount that would be satisfactory to you. It is very much like firing with a kicking gun at a black cat in the dark.

Render bills at short intervals, and be in earnest when you commence to collect them.

THE CARTWRIGHT LECTURES ON THE GENERAL PATHOLOGY OF FEVER.[1]

By WILLIAM H. WELCH, M.D.,

PROFESSOR OF PATHOLOGY IN JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE III.

THE ETIOLOGY OF FEVER.

WE considered in the last lecture the experimental evidence concerning the effects of increased bodily temperature. An advantage of the experimental over the clinical method of investigating this subject is that it enables us to study the effects of heat upon the whole body and its various functions without the intervention of disturbing factors, such as infection, which complicate the clinical analysis of febrile phenomena with reference to this question.

We found that animals may be kept at high febrile temperatures for at least three weeks without manifesting any serious symptoms. The only functional disturbances which could be attributed directly to the influence of the elevated temperature were increased frequency of respiration and quickened pulse. The rapid respiration was found to be due partly to stimulation of the skin by external heat and by the warmed blood, and partly to the action of the warmed blood on the respiratory centres. The quickened pulse could be positively referred to the effect of the warmer blood upon the heart itself. No definite relation could be established between the variations of arterial tension which occur in fever and the height of the temperature.

Although the experiments narrated showed that prolonged high temperature is an element in the causation of fatty degeneration of the heart, they also indicated that other factors, such as infection, are concerned in the production of this lesion. Moreover, experimental evidence was found in support of clinical facts showing that this alteration may exist without serious interference with the functions of the heart, so that the conclusion seems justified that failure of the heart's power in fever is less an effect of high temperature than of other concomitant conditions.

Of the other disturbances in fever we learned that the increased consumption of tissue can be explained only in relatively small part by the elevation of temperature. The lessened perspiration, the renal disorders, and the digestive disturbances (with the possible exception of constipation) are referable also chiefly to other causes than the increased temperature. Both experimental and clinical observations strongly support the view now widely accepted, that the disturbances of the sensorium, which constitute so prominent a part of the group of so-called typhoid symptoms, are dependent in far higher degree upon infection or intoxication than upon the heightened temperature.

Although no attempt was made to analyze in detail the clinical evidence relating to the effects of high temperature, attention was called to the fact that the absence of all serious symptoms in many cases of relapsing fever, and in the so-called aseptic fevers, in spite of prolonged high temperatures, strongly support the conclusions derived from the experimental study of the effects of heat upon man and animals. Even in fevers, such as typhoid fever and pneumonia, where the height of the temperature is undoubtedly a most important index of the severity of the disease, there exists no such parallelism between the temperature and the nature and the severity of the other symptoms as we should expect if these symptoms were caused by the increased heat of the body.

It was emphasized that the results of experimental investigations should not be permitted to control the treatment of fevers, more particularly the use of so-called antipyretic agents. These agents, whether hydrotherapeutic or medicinal, influence, as is well known, many functions besides reducing the temperature. I need only refer to the powerful influence of cold baths upon the circulation and the nervous system, and to the action of antipyrine and other antithermic drugs upon the nervous system.

Reasons were given for assigning to hyperpyrexia and insolation a position separate from other febrile conditions in the discussion as to the effects of elevated temperature.

Before leaving this subject of the effects of increased temperature I wish to call attention to one consideration which should perhaps influence our opinion on this much disputed question. Is it a matter of indifference, so far as the effects of febrile temperatures are concerned, in what manner the increase of temperature is brought about? We have seen that heat regulation, heat production, and heat loss are disturbed in fever; but, as experience shows, not always in the same manner or the same degree. In one case the inco-ordination of the regulating mechanism may be most apparent, the temperature fluctuating strangely up and down; in another case the heat-producing processes are excited to the utmost; and in another the circulatory changes in the skin—the vaso-motor disturbances—are the most prominent phenomena. Now this varying interplay of the factors which cause febrile rise of temperature doubtless corresponds to varying conditions of innervation, of structure, and of function of certain tissues of the body. May we not reasonably suppose that these varying conditions of the tissues directly associated with the rise of temperature may influence their tolerance of increased body-heat? We have not the experimental or the clinical data which would enable us to give a definite answer to the question here propounded, and it would lead me too far from the theme of the present lecture to attempt to sift the equivocal evidence which might be gathered. I suggest this question, however, as one worthy of more attention than it has hitherto received.

I wish now to invite your attention to some considerations concerning the etiology of fever. In this era when etiological studies occupy the foremost rank in medical science, it will naturally be expected that a discussion of the general pathology of fever, even though it does not aim at completeness, will not leave wholly untouched the etiological aspect of the subject.

The general etiology of fever relates mainly to a consideration of the agents producing fever, the so-called pyrogenic substances. It is, moreover, only certain general characters of those agents which can be properly considered here. Most of the questions which at present engage so prominently the attention of physicians concerning the specific causes of individual fevers belong, of course, to the special etiology of fevers, and therefore do not lie within the limits of our subject. But even with these limitations we cannot, in treating of the general etiology of fever, consider the febrile process so much in the abstract as we have done hitherto. We must come into closer contact with the individual forms of fever.

---

[1] Delivered at the College of Physicians and Surgeons, New York, April 12, 1888.

At the start it should be said that probably in no instance are we acquainted with the actual substance or substances upon which the febrile disorder of animal heat immediately and directly depends. We deal here, as elsewhere in medicine, not with direct but with remote causes. But in no department of etiology have we advanced nearer the proximate causes than in many of the infectious fevers. To be convinced of the immense progress which has been brought about by the etiological study of fevers, let one pick up some of the older books on fevers, such as Percy's[1] or Selle's,[2] with their endless divisions into symptomatic genera and species, and their barren speculations. Percy, for instance, describes no less than one hundred and fifteen different kinds of fevers.

In all ages it has been customary to divide fevers into two great groups, viz., those which are secondary to some local cause—usually an inflammation—and those which cannot be explained by the presence of any local lesion. The explanation of the symptomatic seemed so much clearer than that of the essential fevers that attempts have repeatedly been made to place all fevers in the symptomatic group. It is a curious fact that the two methods which have been of the greatest service in the study of fever, each, when first introduced, led to an entire misconception of the nature of fever. Boerhaave, who was the first to make any extensive use of the thermometer at the bedside, supposed that this instrument indicated a reduction of the bodily temperature during the febrile chill. He therefore taught that increased frequency of the pulse, and not the elevation of temperature, is the constant and essential symptom of fever. If we except De Haen's correction, which never became widely known, it was not until the middle of the present century that Boerhaave's error was overthrown. A no less serious misconception sprang from the study of the pathological anatomy of fevers in France during the early part of the present century. The exaggerated ideas of the immediate followers of Bichat, as to what can be accomplished by pathological anatomy, led them to the belief, for a long time widely accepted, that there is no such thing as an essential fever—that all fevers are symptomatic of some local disease. This error of Broussais, one of the most influential and eloquent medical teachers of this century, is plainly traceable partly to the fact that his autopsies were chiefly of typhoid fever, and partly to the belief that the lesions found at the autopsy suffice to explain all of the manifestations of the disease during life. But we need not stop to trace the fate of the various attempts to overthrow the doctrine of essential fevers. I have mentioned one attempt, chiefly on account of the suggestive lessons it conveys rather than from a desire to enter into historical details, which I have hitherto purposely avoided.

The division of fevers into symptomatic and essential fevers is one of undoubted practical utility, and is not likely to be abandoned. But it cannot truthfully be said that this popular classification has been of much assistance in advancing our knowledge. Close inspection shows that the boundary lines between the two groups of fevers are vague and shadowy. Probably no one any longer believes that traumatic fever, the principal type of the symptomatic group, is due to increased production of heat in the seat of inflammation, which, acting like a furnace, was once thought to warm the whole organism, or to the irritation of nerves connected with the inflamed region. The opinion of Billroth and of Weber is now generally accepted, that traumatic fevers are caused by the absorption of pyrogenic substances from the inflamed district. Symptomatic fevers, as well as essential fevers, therefore, are dependent upon the presence within the blood of fever-producing agents. Many essential fevers, moreover, resemble the symptomatic ones in the existence of inflammation or necrosis at the portal where there is reason to believe that the pyrogenic agents gain access to the general circulation. A distinction in these cases cannot be based on the ground that in symptomatic fevers only chemical substances, although possibly the products of bacteria, enter the circulation, and in essential fevers micro-organisms invade the blood, for such a distinction would place cholera, and possibly tetanus and typhoid fever, among the symptomatic fevers. These considerations show how vague and unsatisfactory are the distinctions between symptomatic and essential fevers. Still similar criticisms can be made of many of our artificial classifications which nature is under no compact to observe, and we should undoubtedly be put to great inconvenience if we attempted to dispense with the epithets symptomatic and essential as applicable to different forms of fever. There are, however, other points of view which seem to me more fruitful in the study of the etiology of fever than those embodied in these distinctions. I refer to the differences in the nature of fever producing agents, concerning which our knowledge, although still very imperfect, has been materially increased within recent years. And here again we are greatly indebted to the results of experiments upon animals.

Much light has been shed upon the causes of a certain class of fevers by a series of experiments which received their impulse from the important studies of Alexander Schmidt and his pupils upon the physiology of the blood. A particular direction was given to these experiments by the often-repeated observation that fever and other injurious effects may follow the transfusion of blood, especially when the blood of one species of animal is transfused into an animal of another species. In order to test the supposition that these bad symptoms are due to an excess of fibrin ferment, Köhler[1] injected into the vessels of animals blood made rich in fibrin ferment and fibrinoplastic substance, and found that this blood, when injected in large amount into the jugular vein, causes sudden death by rapid coagulation of the blood in the right heart and pulmonary arteries; but when injected in smaller amount, or in a different manner, produces a typical febrile attack bearing a close resemblance to that following the injection of putrid fluids. Angerer[2] then found that a similar fever, although less intense and more gradual in its development, may be produced by the injection of blood into the peritoneal cavity or the subcutaneous tissue, or even by an extravasation of blood. Although in these experiments it was believed that fibrin ferment is the pyrogenic agent, Edelberg[3] was the first to produce fever and other symptoms of intoxication by the injection of this ferment isolated according to Schmidt's method.

In the light of these experiments it was to be expected that other ferments would be examined with reference to their pyrogenic power. Schmiedeberg[4] discovered that injections of histozyme into the blood of dogs produce high fever associated with general illness, and particularly with diarrhœa. The ferment to which Schmiedeberg has given the name histozyme, he believes to be present normally in small amount in the body, and to be concerned in the dissociation of the nitrogeneous constituents of the tissues. He concludes, from his experiments, that an excessive accumulation in the body of this normal ferment gives rise to fever, with increased metamorphosis of nitrogeneous material. Schmiedeberg thinks it probable that the fibrin-ferment solutions employed by Edelberg in his experiments contained also histozyme, and that the pyrexia was due to the latter substance.

Following these observations concerning the pyrogenic power of fibrin ferment and histozyme, comes the discovery, by Von Bergmann and Angerer,[1] that injections of pepsin and of trypsin into the blood of dogs causes a well-marked fever, with characters like those of the other ferment intoxications described. A valuable calorimetrical study of pepsin and trypsin fevers has been made by Wood, Reichert, and Hare.[2] These authors, as well as Ott,[3] have demonstrated that it is not the pepsin and the trypsin ferments themselves which constitute the pyrogenic agents, but some contaminating substance which seems to be a peptone. That peptones artificially prepared contain poisonous principles has been known for some time, and Brieger[4] has succeeded in isolating a crystallizable poisonous ptomaïne, called pepte-toxin, from commercial peptone and from that formed by the artificial digestion of fibrin. This ptomaïne, however, is not identical with the pyrogenic agent found by Ott and by Wood and his colleagues in commercial pepsin. To this list of pyrogenic substances obtained from impure ferments may be added leucin, and, according to Ott, papayotin and neurin, which produce marked fever when injected into the blood in small quantity. The substance sold under the name of papoid possesses marked pyrogenic power when its filtered aqueous solution is injected into the blood. This substance contains principles belonging to the peptone or albumose group. Dr. Mall, Fellow in Pathology at the Johns Hopkins University, has isolated from commercial papoid a bacillus, which in pure culture exerts a powerful peptonizing action on fibrin and on connective and elastic tissues. The bacillus itself is not pathogenic, but an albumose or some similar substance produced by its activity has pyrogenic power when injected into the blood.

It does not appear that anyone has actually isolated the pyrexial agent from the various ferments employed in these experiments. Certainly no such agent has been obtained in a crystalline form, which is the test of its purity, if we except Brieger's pepto-toxin, the pyrogenic capacity of which has not been established. It has been alleged that the fever-producing agent is the same in all of these ferment intoxications, but this has not been proven nor does it seem probable.

On better grounds, it has been urged by Von Bergmann and Angerer that all of the substances in the group of pyrexial agents now under consideration cause fever by producing the same change in the blood. These authors claim that this change is the formation in the circulating blood of an excessive amount of fibrin ferment, which leads either to coagulation or to stasis in the capillaries, particularly those of the lungs and of the intestines. One of the main arguments for this view is the fall of blood-pressure which Von Bergmann and Angerer observed after injections of pepsin and of pancreatin, but this fall can be explained in other ways than by supposing that the pulmonary capillaries are occluded, and, moreover, Wood, Reichert, and Hare find that the blood-pressure often rises in the course of pepsin fever. It does not seem to me that we are any more able to explain in exactly what manner the pyrogenic substances act in this class of fevers than in other fevers. The idea, however, that the liberation of the fibrin ferment in abnormal quantity is capable of causing fever finds support not only in experiments which have been mentioned, but also in the fact that injections of hæmoglobin solutions and of large quantities of water into the blood produce fever.

But you perhaps by this time have asked yourselves what bearing all of these experiments with various pyrogenic substances has upon the etiology of human fevers. They have in my judgment an important bearing on this subject. However obscure may be the explanation of the mode of action of these substances, however doubtful may be their exact chemical composition, they have certain common characteristics which are calculated to shed light upon the causation of some obscure febrile disorders of human beings. In the first place, the members of this group of pyrogenic substances, if not identical with certain physiological ferments, are readily produced by them, quite independently of the action of bacteria or other micro-organisms. In the second place, some of these substances are present normally in small amount in the body, and if their elimination is impeded or their formation is excessive there is reason to believe that they become efficient causes of fever. In the third place, these pyrogenic substances may be produced, again without the action of bacteria, in extravasated blood or by the abnormal disintegration of tissues, and if they are absorbed from these sources in such a condition or in so large an amount that nature cannot render them harmless they are capable of producing fever. It is customary to call the morbid condition produced by the absorption of these substances ferment intoxication, in analogy with the term putrid intoxication applied to the diseases caused by the absorption of the products of putrefactive bacteria. The term ferment intoxication seems to me to imply more than our knowledge warrants, but it is not of much use to contend against names which have gained currency. It is probable that some of the pyrogenic agents in this group belong to the class of leucomaïnes, but our present information regarding these bodies does not justify any positive statements on this point.

Although the etiology of individual fevers does not belong to our subject, I cannot forbear calling your attention to certain febrile conditions which seem to be produced by the accumulation of substances that are either normal constituents of the body or are the result of chemical processes differing but little from physiological ones

To this category probably belongs the so-called aseptic fever first described by Genzmer and Volkmann.[1] These surgeons have established the fact that there are traumatic fevers not caused by the absorption of septic material and that severe injuries and wounds which pursue an entirely aseptic course are not infrequently associated with considerable elevation of temperature. This aseptic fever is usually to be observed with extensive wounds or injuries in which there is much lacerated tissue or extravasated blood to be disintegrated and absorbed. It occurs not only with wounds correctly treated by antiseptic methods, but also with subcutaneous injuries, particularly fractures of the large bones, where there can be no suspicion of the action of bacteria. Aseptic traumatic fever differs by such marked characteristics from septic fever, that there can be no doubt that the two types of fever are etiologically distinct. Aseptic fever has no prognostic significance; its only symptoms are the elevation of the temperature, which may mount to 104° F. (40° C.), or even 105.8° F. (41° C.), and the increased frequency of the pulse. The entire absence of all of the intoxication symptoms of septic and infectious fevers, such as the benumbed sensorium, the dry tongue and skin, the lessened secretion of urine, I have already referred to in confirmation of the belief that these symptoms are not dependent upon the rise of temperature. Genzmer and Volkmann assign as the cause of aseptic traumatic fever the absorption of substances resulting from the disintegration of the wounded tissues and of the extravasated blood, and state that these substances probably do not differ markedly from those produced by physiological tissue-metamorphoses. This explanation certainly has received decided support by the experiments which I have described in this lecture, a large part of which have been performed since the publication of Genzmer and Volkmann's article. It has been suggested that aseptic traumatic fever is a reflex neurosis and this suggestion cannot be absolutely rejected as a possible explanation, but for various reasons, which cannot here receive further consideration, the usually accepted explanation is the more probable one.

An instructive case of ferment intoxication has been reported by Cramer.[1] There existed in a young woman a cyst the size of a goose's egg between the fibres of the semitendinosus muscle. The cyst was developed from a cavernous angioma and was filled with dark fluid blood. The patient had had fever for almost two years up to the day of the operation. The cause of the fever could not be discovered. Immediately after the removal of the cyst the fever stopped and did not return. In this case the cavernous structure of the cyst-wall accounts for the ease with which we must suppose a considerable quantity of the pyrogenic substance was continuously absorbed from the bloody contents of the cyst. The results of Angerer's experiments already mentioned enable us to explain the source of the fever in this case.

Another instance may be cited, in which fever is probably to be explained by the accumulation within the body of products of normal metabolism. More or less fever appears to be a constant accompaniment of the agonizing method of treatment known as the Schroth cure. In this treatment the patient is kept for a number of successive days on dry food with scarcely any fluids. Both Bartels and Jürgensen,[2] who have investigated the nutritive changes of individuals under this treatment, believe that the body becomes so poor in water that some of the products of regressive metamorphosis cannot be carried out of the system. This certainly seems very probable, and, if true, it affords, in the light of recent experiments, an explanation of the accompanying fever.

I believe that good reasons can be adduced in support of the opinion that the febrile conditions sometimes associated with leucocythemia, profound anæmias, and chlorosis belong to the group of fevers we are now considering. It is possible that some of the obscure ephemeral fevers are also to be included here. But to consider these febrile disorders in detail would lead us into the domain of special etiology, upon which we have already perhaps encroached too far. My purpose has been to bring before your attention only a few clinical examples in illustration of the experimental results.

I think that you will agree with me in the conclusion that experimental and clinical evidence justify us in recognizing as a distinct group of pyrogenic agents substances which have no necessary connection with micro-organisms and which are either not foreign to the healthy organism or are readily formed by unorganized ferments from normal or abnormal constituents of the body. These substances may be described as homologous, in distinction from the heterologous agents concerned in the production of septic and infectious fevers.

A class of pyrogenic agents of far greater clinical importance than those previously considered is formed by the products of micro-organisms which in themselves are not pathogenic. A considerable number of bacteria, which, when inoculated in pure culture into the body, are not capable of further invasion or of multiplication, produce in culture fluids and in dead animal or vegetable material poisonous substances often of great virulence. Exception may be taken to the description of these organisms as non-pathogenic, inasmuch as the products of their activity are poisonous, but the epithet pathogenic is usually assigned by bacteriologists only to such micro-organisms as are capable of multiplication within the body. If we called all of the micro-organisms pathogenic which produce poisonous ptomaïnes we should have to include in this category a far larger number of the known species of bacteria than has hitherto been customary.

The best known and most important of the fevers produced by chemical products of saprophytic bacteria are those grouped under the name putrid intoxication. Until the introduction of the latest era in bacteriology by Koch nearly all of the experimental work on the etiology of fevers related to the causation of the septic and putrid fevers. It is instructive, with our present knowledge, to follow the experiments on this subject from the period of Gaspard, Magendie, and Sedillot up to recent times. What light has been shed upon the mass of contradictory and perplexing results of experiments with putrid fluids by the recent chemical and biological studies of putrefactive processes! Some of the putrid substances experimented with undoubtedly contained parasitic micro-organisms, and others contained only obligatory saprophytes; some were rich in poisonous ptomaïnes, and others were nearly devoid of them. The whole doctrine of the parasitic nature of infectious fevers seems to have hinged in the minds of some upon the determination of the question whether septic and putrid fevers are produced by the absorption of chemical substances or by the invasion of pathogenic bacteria. The ideas concerning putrid intoxication dominated at one time the whole field of fever etiology, and were applied not only to septicæmia but to typhoid fever, typhus fever, yellow fever; in fact, to nearly all infectious fevers. Nor have the echoes of this period even now entirely died out.

Panum was the first to isolate from putrid materials some chemical substance or substances in tolerable purity, certainly free from bacteria. This substance, when injected into animals, produced symptoms of putrid intoxication. Susequently, Von Bergmann and Schmiedeberg isolated from putrefying yeast a poisonous crystalline substance, their celebrated sepsin. For a time the opinion prevailed that this sepsin is the source of all putrid intoxications. Thanks to the investigations of Nencki and others, and particularly of Brieger, we now know that many alkaloidal substances can be separated from putrefying materials. Some of these so-called cadaveric alkaloids or ptomaïnes are poisonous and fever-producing, others are harmless. There is no reason to suppose that the list of the ptomaïnes of putrefaction has been exhausted, nor is it necessary to believe that all of the poisonous constituents of putrefying materials are of an alkaloidal nature.

Most of the bacteria concerned in ordinary putrefactive processes are purely saprophytic. They are incapable of multiplication in the living animal tissues. In a mixture of putrefactive bacteria it is not, however, uncommon to find genuine pathogenic or parasitic bacteria. It was from such sources that the bacilli of mouse septicæmia and of rabbit septicæmia (Koch) were obtained. The bacillus of malignant œdema is also often found in the early stages of post-mortem decomposition.

There is of course no doubt that the absorption of the chemical products of putrefaction may produce fever with septic symptoms quite independently of the penetration and multiplication within living tissues of bacteria.

Here belong certain cases usually described as septic, in which fever and other bad symptoms subside upon the thorough cleansing and disinfection of a foul wound or of a puerperal uterus. The majority of cases of septicæmia are not to be included here, for they depend upon the invasion of pathogenic bacteria. But, excluding the cases of genuine septicæmia, there remain the putrid intoxications which result from the absorption of poisonous substances produced in necrotic or disintegrating tissues or exudations or extravasated blood by the action of purely saprophytic bacteria. The ideas which I have expressed on this subject are now so generally admitted that they require no further elucidation.

It is probable that fever with symptoms of intoxication, although generally of a much milder nature than in the class of cases just considered, may be produced by abnormal fermentations and putrefactions caused by saprophytic bacteria in the alimentary canal. But here the essential morbid conditions seem to be abnormalities in the gastric and intestinal contents, due partly to the character of the ingesta, but chiefly to alterations of the digestive juices.

---

[1] Cramer: Verhandl. d. Deutschen Gesellschaft f. Chirurgie, 13tes Congress, 1884.

[2] Jürgensen: Deutsches Arch. f. klin. Med., Bd. i.

Fermentative and putrefactive bacteria are normally present in the intestinal canal, and have abundant opportunities to gain access to this situation. The number, however, which can multiply and thrive there is quite limited, for under normal conditions, according to Escherich, only such bacteria can multiply to any extent in the intestinal canal as are capable of growing with little or no oxygen, and of deriving their nourishment from the anaerobic fermentation of the food supplied to them in this situation.

Of a far more serious nature are the putrid or ptomaïne intoxications which result from the ingestion of substances which have undergone, outside of the body, putrefaction or changes which lead to the formation of poisonous ptomaïnes. To this group of cases belong at least many of the instances of poisoning which have been caused by eating certain kinds of meat, sausage, fish, cheese, etc. In some of these instances poisonous ptomaïnes have been isolated from the suspected substances, but we know scarcely anything of the micro-organisms which are concerned in their production.

It is important to bear in mind that it is not stinking putrefaction alone which gives rise to poisonous products. Brieger has found that such products may be absent in very advanced decomposition, and that in general the most virulent products are formed in the early stages of putrefaction. We know, furthermore, that putrefactions and fermentations differ in the character of their products. There are differences according to the kind of bacteria present, according to the substances decomposed, and according to various other conditions, such as the presence of oxygen, the temperature, etc. This is not the proper occasion to discuss these details.

Enough has been said to prove that we are justified in recognizing as a second class of pyrogenic agents substances which are the products of bacteria in themselves not pathogenic. These pyrogenic agents may be formed on or within the body, or they may be produced outside of the body. I would not by any means have you infer that it has been proven, in all of the special examples which I have mentioned, that the bacteria involved are not pathogenic or capable of multiplication within the living tissues. We have not sufficient knowledge to assert or to deny this in every instance, but I do not think that it is likely exception will be taken to the classification which I have adopted for most of these cases. As has repeatedly been mentioned, our purpose here is not an analysis of individual cases of fever, but an attempt to classify systematically the various pyrogenic substances.

We come now to the third and most important group of fever-producing agents—the pathogenic micro-organisms. So overshadowing is their importance that it has been claimed that they are the sole causes of fever. In contrast with former times, it is no longer the symptomatic fevers whose etiology is clearest. We have much more definite ideas as to the mode of production of some of the essential fevers which were once the most obscure, than we have of symptomatic fevers. It does not seem to me worth while to go over the chain of evidence which establishes the doctrine that the infectious fevers are caused by micro-organisms. There is probably no one who has thoroughly investigated the subject, and is competent to form an opinion on it, who does not to-day admit that a number of infectious diseases have been proven to depend upon specific micro-organisms, and that it is a logical inference that all infectious diseases are caused by parasitic organisms.

It is not germane to our subject to enter into a morphological or biological description of the different species of pathogenic organisms which are causes of febrile diseases. The only question which concerns us in this consideration of the general etiology of fever, is how the micro-organisms produce fever. Are they themselves the pyrogenic agents, or do they produce chemical substances which are pyrogenic? A number of other possibilities might be mentioned. These and similar questions have suggested themselves to investigators since the beginning of any knowledge of parasitic micro-organisms. Our information is far from sufficient to enable us to answer these questions in a positive manner, and still we are not left wholly to vague surmises in attempting to form some sort of an opinion.

That bacteria can produce mechanical effects by plugging up capillaries and in other ways is certain; but the wide differences presented by the various infectious diseases cannot be reconciled with the idea that pathogenic bacteria act chiefly by mere mechanical interference with the fluid and the solid constituents of the body. Notwithstanding the fact that Stricker and Albert succeeded in producing fever by the injection of starch granules into the blood, probably no one will be inclined to attribute the pyrogenic activity of bacteria in any considerable extent to occlusion of blood-vessels.

In a certain number of infectious diseases, particularly of animals, bacteria are present in such enormous number in the blood and tissues that some are inclined to refer the disastrous effects of the organisms to the withdrawal of oxygen and other nutritive pabulum from the cells of the body. So far as the appropriation of oxygen is concerned, this idea is not supported by the results of most of the examinations of the blood in cases of anthrax. This explanation was more popular in the early days of bacteriology than it is at present, and at the best its value is limited, for it cannot be applied to a large number of infectious diseases, such as cholera or typhoid fever, where the circulating blood is not largely invaded by the parasites. Furthermore, it is not clear how the appropriation by bacteria of nutriment intended for the tissues would help us to explain the production of fever.

It has been suggested that the increased temperature in infectious fevers may be explained by the heat produced by oxidation or other chemical changes in the micro-organisms themselves. But this is not at all a satisfactory explanation. Not only is the quantity of heat which can come from this source in all probability very small compared with that constantly produced in the body, but such an explanation of febrile rise of temperature is not in harmony with what we know concerning the mode of production of fever (see Lecture I.).

The failure to explain the pathogenic power of bacteria in these and similar ways, led to the supposition that the morbid activity of pathogenic bacteria is exerted chiefly by means of injurious chemical products. The demonstration of such products leaves no room for doubt as to the correctness of this supposition for some infectious diseases. This explanation is probable for most such diseases, but experience has shown that it is particularly dangerous to indulge in hasty generalizations in this department of medical science.

Sterilized and filtered cultures, particularly old cultures, of various pathogenic bacteria are capable of producing fever and other symptoms when injected into the blood or tissues. This, of course, makes it evident that the bacteria in question give rise to poisonous substances. It is necessary to distinguish between the intoxication produced by the injurious products of bacteria and the infection caused by the multiplication of the micro-organisms within the body. That this distinction may be readily overlooked, is shown by the recent experiments with the inoculation into animals of pure cultures of the typhoid bacillus. Small quantities of these cultures may be inoculated without any apparent effect; if, however, larger quantities are injected into the veins or the peritoneal cavity of a rabbit, the animal dies in a short time, and the characteristic bacilli are found in the blood, spleen, and elsewhere. It was supposed by Fraenkel and Simmonds,[1] to whom we owe this latter observation, that actual infection took place, but it has been demonstrated by Sirotinin and by Beumer and Peiper[2] that under these circumstances no multiplication of the injected bacilli occurs, and that the same results may be obtained by the injection of sterilized typhoid cultures.

---

[1] Fraenkel and Simmonds: Die Aetiologische Bedeutung des Typhus-bacillus. Hamburg und Leipzig, 1886.

[2] Sirotinin: Zeitschrift f. Hygienc. Bd. i., p. 465; Beumer u. Peiper: Ibid., p. 489.

The isolation in a chemically pure state of the poisonous products of pathogenic bacteria encounters great difficulties, and we owe to Brieger[1] nearly all that has been accomplished in this direction. Two substances which he has obtained from cultures of pathogenic bacteria are of great interest. Brieger isolated from pure cultures of the typhoid bacillus a very poisonous ptomaine, or toxin as he prefers to call this group of substances. He has given to it the name typho-toxin. It may be somewhat significant that he failed to find typho-toxin in a culture which had stood for twenty-four hours at a temperature of 102.2° F. (39° C.). The injection of typho-toxin into guinea-pigs produced great muscular weakness, diarrhœa, increased frequency of pulse and of respiration, and death. Nothing is said as to the effect upon the temperature of the animal.

A toxin has been isolated by Brieger in a crystalline form from an impure culture of the tetanus bacillus. This substance, called tetanin, produces when injected into animals the characteristic symptoms of tetanus.

It is evident that these important discoveries render far more definite than was formerly possible the belief that bacteria produce fever by means of their chemical products.

A dangerous influence exerted by poisonous ptomaines is that under their agency the power of the body of resisting the invasion of various micro-organisms may be impaired or overcome. Thus, Wyssokowitsch has shown that the immunity of some animals against certain species of bacteria may be destroyed by ptomaine-poisoning.

In order to observe the effects upon the temperature I have injected into rabbits sterilized cultures of the typhoid bacillus. Injections of very small quantities of these cultures produce no effects, somewhat larger amounts cause a rise of temperature without other marked symptoms, still larger quantities produce increased temperature, diarrhœa, weakness, and other manifest symptoms of severe illness, but the animal may recover; relatively large amounts are followed by fall of temperature, grave illness, and death. I have also obtained results similar to those of Sirotinin, who inoculated two rabbits with the same amount of a typhoid culture. In one rabbit fever developed and the animal recovered; in the other the temperature fell after the injection and the animal died. This certainly does not indicate that the rise of temperature in itself is an unwelcome attendant of intoxication with the poisonous products of bacteria. My experiments certainly showed that the animals were more likely to die after injection of typhoid cultures when the temperature fell than when it rose, independently of the quantity of material injected. One is reminded here of the very malignant cases of typhoid fever reported by Fraentzel and others, in which the temperature throughout a great part of the disease was subfebrile, or even at times subnormal.

In no disease is the dependence of the febrile paroxysm upon the presence of bacteria so apparent as in relapsing fever, where, according to the statements of most, although not of all, observers, the spirilla appear in the blood at the beginning of a paroxysm and disappear at the end. Whether or not here and in malaria the pyrogenic agent is a chemical product of the micro-organisms, causing the disease, we do not know.

I must content myself with having brought before you evidence showing that, at least in some of the infectious fevers, the specific bacteria produce pyrogenic substances. We have no right to say that this is the only way in which pathogenic bacteria can cause fever.

We have considered now three groups of agents concerned in the production of fever, viz., first, unorganized ferments and other relatively homologous substances; second, ptomaines and other chemical products of saprophytic micro-organisms; third, pathogenic micro-organisms and their chemical products.

It is not to be understood that these groups correspond to sharply defined classes of fever-producing agents. The same substance may be produced by the action of unorganized ferments as well as by saprophytic bacteria, or by parasitic bacteria; hence we may find the same fever-producing agent in each of the three groups. As has already been mentioned, our knowedge does not justify us in regarding these various substances as the immediate and direct pyrogenic agents. The epithet pyrogenic is applied to them only by a certain latitude of signification. It is possible that these various substances which we are in the habit of describing as pyrogenic may produce in the body some common change which gives rise to the real fever-producing agent. This is the view of Von Bergmann and Angerer, who believe this common change is a liberation of fibrin ferment by destruction of leucocytes. While we cannot consider this view as more than an hypothesis, it is, nevertheless, well to remember that apparently heterogeneous substances which are usually designated as pyrogenic may produce similar changes, which are to be regarded as the real source of the febrile disorder of animal heat. But, notwithstanding these limitations and these elements of uncertainty, it seems to me that some such classification as that suggested of the agents producing fever is more useful than that usually employed in the discussions of the etiology of symptomatic and of essential fevers.

There is one point which must be impressed upon every one who makes many experiments with pyrexial agents. This is that once in a while a substance of undoubted pyrogenic power causes a fall instead of a rise of temperature. This occurs frequently when the substance is injected in large quantity, and under these circumstances there is usually produced a condition of collapse. But in exceptional cases the same dose which will cause in one animal a rise of temperature may give rise in another animal of the same species to a distinct reduction of temperature. In these latter cases there must be some idiosyncrasy on the part of the animal. Aronsohn[1] refers this unusual phenomenon to some peculiarity of the heat-centres in the brain, and he draws an interesting parallel between this contrary effect of pyrogenic substances and the exceptional cases in which antipyretic drugs give rise to elevation instead of lowering of temperature.

The causes of fever which we have thus far discussed have been substances which exert a pyrogenic effect when introduced into the circulation. We suppose that these substances act in some way upon the nervous system, but whether or not this action is a primary one it is impossible to say. Even if we assume, as is often done, that these substances incite directly in the blood and tissues chemical changes which lead to increased production of heat, we must still have recourse to some action upon the nervous system, as has already been sufficiently set forth in the previous lectures.

It cannot be doubted that fever may be caused by other agencies than pyrogenic substances present in the blood or tissues. The effects of exposure to external heat have already been considered. We found experimental evidence in support of the view ably advocated by N. C. Wood, that in typical cases of thermic fever, or sunstroke, the strain placed upon the heat-regulating centres by exposure to excessive heat results in paralysis of these centres, with rapid elevation of the external temperature.

The cause of the elevation of temperature in tetanus is not altogether clear. In this disease the temperature may vary but little from the normal, but it is not uncommon to find excessive elevations of temperature toward the termination. Temperatures of 113° F. (45° C.) or more have been recorded. The idea would naturally suggest itself that the rise of temperature is due to the tetanic muscular spasms, which we know to be accompanied by production of heat. Leyden was led to adopt this explanation by the results of experiments made upon animals. He succeeded by producing violent tetanic contractions of the muscles of a dog in raising the internal temperature in the course of one hour and a half from 103.3° F. (39.6° C.) to 112.6° F. (44.8° C.). Clinical observations, however, do not support the supposition that the hyperpyretic temperatures of tetanus are dependent upon the muscular contractions. In spite of violent and prolonged tetanic spasms, the internal temperature may remain normal or be but slightly elevated. There is a decided similarity between the hyperpyrexia of tetanus and that which occurs in rheumatism and some other diseases, particularly in affections of the central nervous system, and it certainly seems probable that in all of these cases there is a profound disturbance of the heat-regulating centres. As the elimination of urea in tetanus is not excessive, we find additional reason to separate tetanic hyperpyrexia from ordinary febrile conditions. Recent investigations of the etiology of tetanus have rendered it certain that at least some forms of this disease are caused by infection with a special micro-organism. This has been demonstrated not only in the tetanus of animals but also in that of human beings. The tetanus bacillus has been found wide-spread in the ground in Germany, and I find it abundant also in the ground in Baltimore and its neighborhood. In experimental tetanus the specific bacillus, which has not yet been obtained in perfectly pure culture, develops chiefly in the tissues near the seat of inoculation, and does not invade other parts of the body and the blood to any great extent. This indicates that the symptoms are referable chiefly to poisoning by some chemical products of the specific micro-organism. As has already been mentioned, this view is sustained by Brieger's discovery in cultures containing the tetanus bacillus of a peculiar ptomaine which he has called tetanin, and which produces tonic spasms of the muscles. It is therefore reasonable to believe that the hyperpyrexia of tetanus is caused by the action of poisonous products of the tetanus bacillus on the nervous centres concerned in temperature-regulation. Our present knowledge, however, does not warrant us in asserting that all forms of tetanus in human beings are of an infectious nature.

[1] Brieger: Untersuchungen uber Ptomaïne. Berlin, 1886.

[1] Aronsohn: Deutsche Med. Wochenschrift, 1888.

In the first lecture of this course evidence was presented to show that pyrexia may be caused by affections of the nervous system without the agency of any pyrogenic substance. It may jar upon the sensibilities of some to call this form of pyrexia fever; but this hesitation can be due only to the idea that symptoms which are referable to infection or intoxication are essential to the conception of fever. In my judgment, we shall be led into confusion if we attempt to incorporate into our definition of fever more than properly belongs to the febrile disorder of animal heat, and from this point of view there can be no impropriety in designating as fever the pyrexia dependent directly upon affections of the nervous system.

It is not necessary to repeat here the conclusive experimental evidence for the existence in the nervous system of centres or regions which control the dissipation of heat, and the chemical processes concerned in the production of heat. Those who are not much impressed by experiments upon animals can hardly fail to be convinced by the clinical evidence, which demonstrates that lesions of the nervous system may cause elevation of temperature which cannot be referred to the action of any pyrogenic substance. Such evidence must of course be collected from cases where the fever cannot be explained by inflammation, bed-sores, or other lesions which can give rise to absorption fever.

W. Hale White,[1] in the interesting article already referred to, has collected a number of cases of tumor, hemorrhage, softening, sclerosis, injury, and functional disturbance of the spinal cord and brain, in which the pyrexia or hyperpyrexia is to be explained only by the lesion of the nervous system. The number of such cases might be considerably increased. These cases show that lesions of the cervical part of the cord, of the pons, of the corpus striatum, and of the neighboring white matter are most likely to be associated with high temperature; but the cases hitherto reported hardly justify positive statements as to the exact situation in man of thermically active nerves or regions in the brain and spinal cord. As might be expected, not only focal lesions, but also diffuse diseases, such as occur in general paralysis of the insane, locomotor ataxia, multiple sclerosis, may give rise to pyrexia which sometimes assumes the form of temperature crises. It is in harmony with what we know of other disorders of the nervous system to find that, not only demonstrable anatomical lesions, but also functional disturbances, may produce nervous pyrexia. Such functional disturbance furnishes the most probable explanation of the singular and erratic elevations of temperature which have been occasionally observed in hysteria.

A question which merits more consideration than it is possible to give to it on the present occasion relates to the possibility of the occurrence of fever as a reflex neurosis. The advance in our knowledge of the etiology of traumatic and inflammatory fevers has pushed aside almost wholly the old doctrine of irritative fever. There are, however, cases of fever where still the simplest and apparently most rational explanation of the causation is peripheral nerve irritation. As examples may be mentioned the fever resulting from teething in children, that sometimes accompanying the passage of gall-stones or urinary calculi, and that occasionally following the insertion of a catheter into the urethra. It must be admitted that the evidence on this point is not conclusive. Especially is there lack of satisfactory experimental evidence. Electrical irritation of the exposed sciatic nerve is, under ordinary circumstances, followed by a moderate fall of temperature, although Ott[1] finds that in atropinized cats such irritation is followed by a decided rise of temperature. But these experiments cannot be held to weigh for or against the doctrine of irritative fever. Observations on human beings indicate that peripheral nerve irritation, if ever a cause of fever, is so only in certain situations, and under certain forms of stimulation, and in certain individuals. In infants temperature regulation is more labile than in adults, so that it may be that nerve irritation can more readily disturb the temperature in the former than in the latter. The chief controversy as to the question now before us has been as to the explanation of certain forms of urethral or catheter fever. It cannot be doubted that a large number, probably most, of the cases of so-called urethral fever are instances of genuine absorption fever. Even if we exclude all cases with diseased kidneys, or with cystitis, or other inflammatory disease of the urinary passages, there remains a certain number of cases in which the gentle insertion of a disinfected catheter is followed by distinct febrile reaction. It seems unwarrantable to assume that in all of these cases the catheter has caused a laceration of the urethra through which pyrogenic substances are absorbed. What is the nature and whence the source of these substances? In the cases now under consideration they can be sought only in the normal urine, and of their existence there no proof has been afforded. In these cases it is certainly very difficult to understand how the fever can be interpreted as due to the absorption of some pyrogenic agent, and, failing this explanation, the idea that the fever is dependent upon nerve-irritation is most plausible.

I have now presented to you an imperfect survey of the general etiology of fever. The attempt has been made to classify the leading causes of fever, but it cannot be claimed that every variety of fever can be assigned to one of these groups of causes. Our knowledge of the etiology of special fevers is still too imperfect to warrant any such generalization. This is an attractive field for much patient investigation. I need only remind you of the uncertainty which still pertains to the causation of many of the fevers of warm countries. There is reason to believe that there remain yet to be differentiated etiologically specific types of fever which occur among us, and particularly in our Southern States. It may be that increasing knowledge will necessitate the recognition of varieties of pyrogenic agents entirely distinct from any with which we are now familiar. It is certain that future investigations will add clearness and precision to our ideas of the nature and mode of action of causes of fever, which at the best we can now understand only imperfectly.

[1] W. Hale White: The Theory of a Heat-centre from a Clinical Point of View. Guy's Hospital Reports, vol. xlii., 1884.

[1] Ott: Therapeutic Gazette, August, 1887.

I cannot conclude this course of lectures without saying a word on a subject which must engage the attention of everyone who gives much thought to the nature of fever. What is the significance of fever, is a question which thrusts itself upon us no less than it has upon physicians in all ages. Unfortunately, we cannot to-day, any more than could our predecessors, give other than a speculative answer to this question. There have been in all ages enlightened physicians who have held the opinion that fever is a process which aids in the elimination, or destruction, of injurious substances which gain access to the body. Under the influence of ideas which sought in increased temperature the origin of the grave symptoms of fever, we have, in recent times, in great part lost sight of the doctrine once prevalent, that there may be in fever a conservative element. There is much which speaks in favor of this doctrine. The real enemy in most fevers is the noxious substance which invades the body, and there is nothing to prevent us from believing that fever is a weapon employed by nature to combat the assaults of this enemy. The doctrine of evolution indicates that a process which characterizes the reaction of all warm-blooded animals against the invasion of a host of harmful substances has not been developed to such an extent, and is not retained with such pertinacity, without subserving some useful purpose. This is a point of view from which many pathological processes can be regarded with advantage. Even suppuration, which one does not generally look upon as a beneficent provision, is a most important instrument of nature in forming a barrier against general infection of the body with certain micro-organisms. It is impossible, with our present knowledge, to say in exactly what way fever accomplishes a useful purpose. There are facts which suggest that in some cases of fever the increased temperature, as such, may impair the vitality, or check the virulence, of pathogenic micro organisms; but there are many circumstances which make it difficult to suppose that this is the agency by which fever usually exerts a favorable action. The supposition seems to me more probable that the increased oxidation of fever aids in the destruction of injurious substances. According to this view, the fever-producing agents light the fire which consumes them. It is not incompatible with this conception of fever to suppose that the fire may prove injurious also to the patient, and may require the controlling hand of the physician. Time will not permit me to elaborate further the ideas here suggested. In the course of these lectures, some facts have been presented, and others might be drawn from clinical and experimental observations, which favor the hypothesis that fever is, in a certain sense, a conservative process. Unproven and intangible as the hypothesis may seem to some, no apology is needed for bringing to your attention a conception of fever in favor of which much can be adduced, and which, if true, is of fundamental importance, both theoretically and practically.

EARS.—According to Aristotle large ears are indicative of imbecility; but happy is the man who has square ears, for they are a sure indication of sublimity of soul and purity of life. Flat ears denote a coarse and brutal man; small ones announce bad temper and madness, while those of fairest promise are firm and of middling size.

IS VISION EVER PERMANENTLY AFFECTED BY SUNSTROKE?[1]

By JAMES A. SPALDING, M.D.,
PORTLAND, ME.

DURING the last five years I have examined a large number of persons claiming pensions for various diseases of the eye, and I had prepared for publication a paper based upon the entire list of cases. But since such a paper would open up too many subjects, I have abstracted a few cases illustrative of the assertion that sunstroke in the army in 1862 to 1865 caused blindness ten or more years later, and have appended a brief summary of the accessible cases of insolation with subsequent defective vision.

It is hoped that some members may be able to recall their experience in this respect, and thus enable pension examiners to obtain some foundation for proper judgment in regard to the question which is so frequently asked, yet still remains unanswered, whether sunstroke is ever followed by permanent blindness or great loss of sight.

I use the word permanent advisedly, because the mind is so often disturbed after any sudden cerebral disorder, that the sufferer's assertions are not trustworthy. Thus, after fainting, it is quite common to hear the patient speak of being suddenly "struck blind," or of "mist coming over the eyes." Now a soldier might remember that at the time of his sunstroke he lost his sight temporarily, and yet many years after when more or less weak of sight from entirely different causes, and hearing of other soldiers obtaining pensions for no visible disease, he would renew this recollection, and make it the basis for a fraudulent claim.

What I would desire, therefore, and it is certainly a question of public interest, is a discussion of the permanent results of sunstroke upon vision, so that we may learn whether we are justified in recommending any pension for any degree of blindness following insolation many years before. The question may at first sight appear frivolous, yet it is so often raised, and as often unanswered, and so long as experts are employed to detect swindling pension claimants, it is well for them to be supported by more accurate knowledge upon this interesting subject than they can now find in any text-books.

The first claimant alleges that he was sunstruck in 1863, and soon after discharged for general debility and an affection of the eyes, the precise nature of which could not be discovered owing to the absence of documents. Careful examination reveals total loss of sight from cataract in each eye. But we must seek further than this for the loss of sight, because an eye otherwise healthy but simply cataractous from senility can easily distinguish the light of a lamp at several feet, while it also possesses a perfect visual field. But here a bright flame can be discerned only at one foot in one eye, and at even less distance in the other, while by repeated tests we find that the field of vision is contracted. We have, therefore, the right to assume that the claimant's blindness depends rather upon a retinal or optic nerve affection than upon simple senile opacification of the lens.

The second case is that of a soldier who had long been suffering from malarial fever. Soon after returning to duty he was violently sunstruck. He remembered losing his sight while swooning from the effect of the heat, but he was equally sure that when he recovered his senses his sight was as good as ever. He soon resumed active duty, and served more than a year, when he was again stricken with malarial fever. Later still, he suffered from asthma and pneumonia, till he was reduced to a shadow. Within a few months after his discharge in 1865 for total debility, the sight of one eye began to fail and then that of the other, till in 1868, after being treated by numerous general practitioners, he came under the care of an ophthalmic surgeon who diagnosticated white optic atrophy. My examination shows total blindness in each eye due to optic atrophy.

---

[1] This paper was read at the last annual meeting of the American Ophthalmological Society, but no member then present had ever heard of the sight being affected by insolation. I now publish it, in the hope that those surgeons who served during the war, saw soldiers sunstruck, and who followed those cases afterward, may give us information on this point, and thus increase our knowledge of a subject which is important in more points than one.

This claimant, though sunstruck, did not even pretend that this had anything to do with his blindness, for he volunteered the remark that for two if not three years thereafter he could read the finest type with each eye alone.

The third case, and a curiously typical one, is that of a soldier who testifies that he was sunstruck while on picket duty in 1864. and, though not discharged till four months later, did no active duty after that. While in the hospital recovering from the insolation, his hearing and sight began to be affected. Year after year this double trouble "increased," until, according to his story, he is now extremely deaf in the left ear, and blind in the left eye.

We soon find that the pretended loss of sight is simply a high degree of hypermetropia, for with suitable glasses he is made to acknowledge 20–30 in one eye, and 20–50 in the "blind" eye. And further still, the finest type can be read perfectly with either eye with the proper presbyopic glasses superadded to the degree of hypermetropia.

The fourth claimant wants a pension for total blindness, because he was sunstruck in 1864, came home the next year with weak eyes, and worked as well as any other farmer till 1880, except that his eyelids were red and his eyes "weak." In that year he lost the sight of the right eye, and two years later that of the other eye. He is now totally blind, and the ophthalmoscope shows optic atrophy.

Here now are four cases of loss of sight following insolation, yet the asserted symptoms vary widely. One urges total blindness in both eyes dependent on insolation, and the defects in the visual field seem to justify us in the belief that there may be some connection between the two affections. The second is severely affected by sunstroke, is unconscious for hours, yet recovers without any eye disease, and serves actively for a long time, his final blindness, though total, being referred to exhaustion and spinal irritation. The third claims that sunstroke made him almost blind in one eye and deaf in one ear, and then, at a later date, affected the other eye and ear. Nevertheless, the tests show that the sight is good in both eyes, and that the deafness is slight, and, on the whole, may rather be referred to catarrh than to insolation. The fourth patient had a sunstroke during the war, but has no trouble except "weakness of the eyes" till 1880, when he loses his sight in one eye, and then in the other, from optic atrophy.

Verily, the results of insolation upon the sight are manifold when we listen to pension claimants' complaints!

How can we decide in such perplexing circumstances? If we search ophthalmological literature we find but few cases bearing on this point. And to be precise, has there ever been published more than one genuine case in which a patient became totally and irredeemably blind within any reasonable time after a genuine attack of sunstroke?

Among the doubtful cases we may first quote that recorded by Hamilton:

A young man who had been drinking heavily on an extremely hot day, was apparently sunstruck, grew dizzy. fell unconscious, and on recovering his senses found that his sight was greatly impaired. Ten days later (though no mention of his drinking is made) he was again affected in the same way, with renewed and increased loss of sight. From the time of the last attack his head ached constantly, and his former habitual epistaxis ceased. After years of fruitless treatment he could barely decipher Jaeger 20; optic papillæ chiefly swollen and hyperæmic, but partially pale and atrophic. Repeated bloodletting soon relieved the headache, and greatly improved the sight.

Galezowsky reports the case of a boy, five years of age, with convulsions and loss of consciousness on a very hot day; total blindness and vomiting; four weeks later infiltration about the papillæ; flying blisters and potassic iodide restored the sight in a few weeks.

The same authority cites three cases of atrophy of the optic nerve dependent on insolation among 168 cases of optic atrophy from every cause, yet Schoeler, among 188 cases of the same disease, and Peltesohn, among 496, were not able to find a single one in which there was any history of exposure to the sun.

Hutchinson mentions, with an interrogation mark, a case of double optic neuritis and partial atrophy in which the patient had been exposed to excessive heat. But in his list of 248 cases of optic atrophy he speaks of but three in which there could possibly have been a sunstroke, for they alone were exposed to the sun in the tropics (evidence of but slight weight when we recall the innumerable causes of atrophy), but after all there was no direct history of insolation.

Brough saw a young girl with vision of less than 20–200, subsequent to a sunstroke, and remaining in this condition for over two years while under his observation. (There is nothing to show that this case may not have been one of hysterical amblyopia.)

Mooren has seen double optic neuritis after (how long after?) insolation, but I do not understand that he refers this condition to the sunstroke, nor does he inform us of the result.

Thus, after carefully examining every accessible case of disturbance of vision which might in any conceivable manner be referred to insolation, I can truly say that the only trustworthy ones are those reported by Hotz and Hulke.

Hotz examined six persons ophthalmoscopically, soon after exposure to the intense heat of a summer sun, and found the following conditions:

CASE I.—A man, aged twenty-eight, imperfect paralysis of the left arm; fingers counted accurately at six feet; loss of entire right visual field, nasal half of each optic papilla swollen.

CASE II.—A woman, aged forty-one, optic neuritis, right eye.

CASE III.—A man with the same condition in the right eye.

CASE IV.—A man, aged forty-eight, optic neuritis in each eye. Vision of right eye, 20–50, of left eye, 20–200.

CASE V.—A man, aged thirty-two, left optic neuritis, fingers counted at ten feet.

CASE VI.—A woman, aged twenty-four, vision of right eye normal, excessive hyperæmia of the fundus of the left eye, with only bare perception of light, optic neuritis in the left eye.

I have not been able to refer to the original paper, but Burnett, who reviewed it in Knapp's *Archives*, says that a good recovery was made in each case.

Finally, and unique in its history of a permanent effect upon the sight, is Hulke's case of a perfectly healthy woman, aged twenty-four, who was sunstruck. Loss of consciousness was followed by left hemiplegia, convergent strabismus, diplopia, and loss of sight. A fortnight later the pupils were fully dilated and immovable; total blindness in each eye. Optic neuritis. Six months later, no sight in either eye, white optic atrophy.

All accessible literature leads us to doubt if any soldier is entitled to a pension when he asserts that he lost his eyesight from insolation. The probabilities are that, when one is sunstruck, the loss of sight referred to as the cause of the subsequent weakness of the eyes, or of the blindness, is simply the result of incipient loss of consciousness, or, according to Hotz's observation, of a neuritis from which recovery is sure; and, further, when anyone claims that his eyes were "weak" from sunstroke, and that he only became more or less blind years afterward. the probabilities are that he is a common swindler.

Nevertheless, we must not forget that at the London Congress, in 1881, Sir Joseph Fayrer spoke of partial or complete blindness as one of the *usual* results of insolation.

From the reports of that meeting, however, it is plain that recent blindness after sunstroke is meant, not that occurring many years later.

After duly considering these facts, and bearing in mind the impaired field of vision in the first case, I could see no reason why the man should have a pension for sunstroke-blindness, but many why he should have one for optic atrophy, due to exposure. Further still, he was discharged for debility and defective vision, so that a full pension was due for blindness, independent of the cataractous loss of sight.

In Case II., a pension was recommended, not for blindness due to insolation, for the claimant repeatedly declared that after sunstroke he could see as well as ever, but for spinal atrophy.

The third claimant was too plainly a fraud; he could read newspaper type by the hour, and had competed successfully for years in a factory with men who did not pretend to be blind even of one eye.

The fourth claimant was also a swindler, as his story proves, for no one ever heard of "weak" eyes, *i.e.*, blepharitis and conjunctivitis changing into optic atrophy, fifteen years after a slight insolation. Nevertheless, the man obtained a full pension for total blindness, because he was a "deserving" man. And yet it was notorious that no one in the town used so much tobacco. How much more probable that overuse of tobacco made him blind?

I do not know whether this advice has been followed by the department. The expert may have the best inclination to help the soldier, but it is his duty to judge cases from the standpoint of scientific truth, not from that of the false and fashionable policy of catching practice or fees from the pensioners or their friends. Nevertheless, as my experience goes, it is almost useless to give any but a favorable opinion in every case; if not done, the department is besieged till success is attained.

It is my opinion that insolation rarely affects the sight permanently, and if so, that the results in the form of optic atrophy ensue within a few months, never, as the innumerable pension claimants assert, at any interval extending from four to nineteen years later.

Hebra's Water-Bed.—At the meeting of the Surgical Section of the Suffolk District Medical Society, on March 7th, Dr. Otis K. Newell read a paper on "The Surgical Use of Hebra's Continual Bath or Water-bed," of which he had had personal observation. In addition to its use in the treatment of eczema and other cutaneous diseases, the continual bath has been used with success in the treatment of gangrene, bedsores, etc., and more especially severe burns, where its beneficial effects are particularly noticeable. Patients are sometimes kept in the water for a very long time. One patient was in the bath 385 days. They are removed only for evacuation of the bowels and bladder, and they take their meals and sleep when in the water. The danger of drowning is much less than seems apparent at first thought. If a patient is very weak the precaution may be taken to support him by a bandage passing around the body under the arms, which is secured at the head of the bath to prevent his slipping down the inclined portion that raises the head out of water. Only the palms and soles suffer, and these only during the first few days. They become shrivelled and folded like a washerwoman's hands, and the condition is much alleviated by applications of substances of a greasy nature. A papular eruption occurs on the parts which are both in and out of the water, as the arms and thorax. This, however, heals spontaneously. Hebra's beds contain 675 litres of water. When a patient first enters the bath the temperature of the water is 30° C. (86° F.), which seems warm to him. The heat is gradually raised to 35° or 37° C. (95° or 98.6° F.), which is kept constant by a simple arrangement by means of a kerosene lamp.

The Eastern Dispensary which charges for prescriptions, and pays its medical staff, is prospering.

HYSTERICAL FEVER.

By FRANK C. BRESSLER, M.D.,
BALTIMORE, MD.

I desire to call attention, in the following paper, to an affection which, as far as I am aware, is not described by authors generally, but of which I have encountered several cases. I have ventured to describe the affection under the name of hysterical fever.

By hysterical fever I mean a perverted condition of the nervous system occurring in a neurotic individual, attended by elevated temperature which may last from a few hours to several days, and associated throughout its duration by more or less symptoms of an hysterical character.

Every physician, in his practice among the female sex, has undoubtedly noticed that some trivial cause has thrown his patient into a febrile condition which has lasted for two or three hours, or longer. He mentally calls such attacks, perhaps, neurotic fever, and then forgets the occurrence until the same condition occurs again in some other patient.

No doubt exists in my mind, whenever I hear of a physician who has attended a large number of typhoid fever cases and has never lost any, that he has had some cases of hysterical fever among them, and has called them typhoid fever with hysterical symptoms predominating.

This fact has some little bearing on statistics, and on the various results obtained by the different methods of treatment. I, of course, do not mean to be understood that all cases of typhoid are erroneously diagnosed, but if only a few cases occur, the result makes a difference.

With these few explanatory words, we will speak of the various phases of hysterical fever, as far as observed.

As to the anatomical changes, we know nothing. It probably depends on the same changes that occur in hysteria, with an additional influence, which so operates on the thermic centre as to destroy its inhibitory influence, thus giving rise to elevated temperature.

The clinical history is as variable as the various manifestations of hysteria. It generally begins with symptoms simulating mild intermittent fever—chilliness, susceptibility to atmospheric changes, loss of appetite. The bowels tend to be sluggish; in one case, however, diarrhœa was present for two days. Tongue coated, headache variable in severity, general malaise, temperature elevated, face generally flushed, or there is a circumscribed flush limited to the cheeks. Lips tend to scale and crack early; the eyes are clear and brilliant; the mind is bright, comprehension quickened, so that a dull mind may become comparatively bright and keen. General hyperæsthesia, both to muscular and cutaneous impressions. The special senses of hearing, tasting, smelling, etc., are rendered more acute. No true delirium is present (at least there was none in my cases), no matter how severe the attack seems to be. Patients are quite irritable, so that trivial noises may annoy them considerably, and this is followed often by tremors and marked rise of temperature.

The appetite is often perverted, the patients asking for those things which are generally contra-indicated in febrile conditions. The most annoying thing the physician has to contend with is the great irritability of the stomach. Things most easily digested often cause considerable gastric uneasiness, this, of course, depending much upon the whims of the patient. One of the most important things, however, is the vomiting, which is often so persistent that ice-water or anything introduced into the oral cavity may provoke it. This symptom was present in all of my cases, and, in spite of every means I adopted for its arrest, ran its own course. Owing to this fact, the patients persistently refuse to take food, pleading the fear of vomiting being excited. Oftentimes several days have gone by without one ounce of food passing their lips, though, of course, water or ice is craved and taken.

The abdomen is extremely sensitive to pressure, so that it can barely support the weight of the bedclothing. Borborygmi are often present. This sensitiveness may lead to an erroneous diagnosis of peritonitis unless caution be observed. It is differentiated from the latter by the fluctuating character of the pains, absence of tympanitis, absence of an exciting cause, variability of temperature, etc. Added to these, the hysterical symptoms and the ovarian pain on pressure make its exclusion comparatively easy.

Cramps, or neuralgia of the bowels, were pronounced symptoms in two cases; the same were characterized by the persistence of the pain and its obstinacy in responding to medication, heroic doses of morphine failing often to give relief.

Insomnia proved to be a troublesome thing in one case; oftentimes this patient lay from thirty-six to forty-eight hours obtaining barely one hour's sleep.

No marked changes were observed in the respiratory organs, beyond temporary increase of the respiratory acts, depending upon functional disturbances. Hysterical asthma was present to a mild degree in one case.

The pulse varied, being generally increased in frequency, often reaching 120 per minute, and rarely falling below 85. This condition likewise depended upon the surroundings of the patient.

The temperature is peculiar. It varies from 101 to 105° or more, and usually attains a high degree early in the disease. In my cases, the temperature reached a high point on the second day. This elevated temperature may last from a few days up to weeks, when it suddenly drops to nearly normal again, perhaps to rise as rapidly as it fell. It is highest in the evening, coming down 1–4° by the morning, or the reverse may be the case. It may be 99° one hour, and two hours later jump to 105°. One of my cases had an evening temperature of 103°, with a morning remission of 1–5 for three days, and from this fact typhoid fever was diagnosed and concurred in by another physician. This supposed typhoid temperature occurred, however, in the third week of her illness; two days later it dropped down to 99.4°, and was followed on the succeeding day by a jump to 105°, owing to the patient having been angered. This illustrates the variability of the temperature in this condition; any exertion, whether mental or muscular, may cause a most marked change in the temperature.

With this elevated temperature, one thing was very noticeable, namely, that little wasting of the body took place as compared with that which occurs in other diseases of a like duration and temperature, with this one more point, that the patients regain flesh rapidly after the disease has come to a close.

Menstruation may be interfered with, and in one case suppression existed for two periods.

Marked ovarian sensitiveness was observed in all my cases, so that pressure upon the ovaries elicited the characteristic pains observed in the hysterical condition.

No plain symptoms referable to the urinary apparatus were observed. The urine, however, was not examined.

With the above-mentioned symptoms a great many other ones were noticed, but being of no important moment, they were not recorded.

As to the duration, that depends on the circumstances and surroundings of the patient. It may last but a few hours or several weeks; oftentimes they have an intermission of days, from which we may pronounce our patient well, only to be disappointed by a return of the former febrile condition.

The prognosis, no doubt, is the same as that of hysteria—namely, good.

The treatment is also the same as that for hysteria, with the addition of some febrifuge, the one giving most satisfaction being antifibrine rubbed up with a little gum acacia. Persist in making your patient take food, in small quantities, however, and treat all symptoms on general principles as they arise.

In the description I have given of hysterical fever I am not able to say positively that all cases of it will run the same course as mine did; neither can I say that I have pointed out any symptoms that are pathognomonic of it, thereby placing hysterical fever on a proper footing. I hope, however, that I have pointed out the fact that such a condition as hysterical fever exists. Finally, in support of my opinion, I find, on looking over various journals, an article entitled "Hysterical Fever," by De Bove, described in the *Therapeutic Gazette* for May 15, 1885.

1711 Bank Street.

THE MORTALITY OF EPILEPSY.

By WILLIAM L. WORCESTER, M.D.,

ASSISTANT PHYSICIAN TO THE MICHIGAN ASYLUM FOR THE INSANE AT KALAMAZOO.

So far as my reading has extended, writers on the subject of epilepsy, with few exceptions, either say nothing of the possibility of a fatal termination of the disease, or speak of such an event as of rare occurrence. I have never seen any attempt to estimate the frequency with which it proves fatal. My own observation, during my connection with this institution, has led me, on the contrary, to consider epilepsy, in its severer forms at least, as a very deadly disease, and as this impression is fully borne out by the records of this and the reports of other similar institutions, it has seemed to me that a publication of the statistics which I have collected might aid in correcting what seems to me a prevalent error on this subject.

The Michigan Asylum for the Insane has been in operation for twenty-eight years. Up to October 1, 1887, 4,525 admissions had been recorded. Excluding readmissions, 4,084 patients had been treated, of whom 234 were epileptics. I have carefully examined the histories of these cases, and excluded all in which there seemed to me to be a reasonable doubt in regard to diagnosis.

The following table shows the number of epileptics of each sex treated up to the above date, with the number of discharges and of deaths occurring while under treatment.

TABLE I.—*Showing Results in 234 Cases of Epilepsy treated up to October 1, 1887.*

	Males.	Females.	Total.
Discharged	58	52	110
Died	37	25	62
Remain	40	22	62
Total treated	135	99	234

It will be seen that 62, or 26.5 per cent. of the whole number treated, died. This is a much larger percentage of deaths than has occurred in the general population of the Asylum. Out of the 4,084 patients treated, 735, or eighteen per cent., have died.

This disproportionate mortality has not been due to an increased liability to other fatal diseases, as will appear from the following table, showing the causes of death in the cases which died.

TABLE II.—*Showing Causes of Death in 62 Epileptics.*

	Males.	Females.	Total.
Epileptic convulsions	12	7	19
Status epilepticus	10	7	17
Œdema of lungs, following convulsion	1	1	2
Exhaustion from epilepsy	4	3	7
Phthisis pulmonalis	2	4	6
Diphtheria	1	.	1
Traumatic	..	1	1
Endocarditis, ulcerative	1	.	1
Gangrene, senile	1	..	1
Dysentery	1	..	1
Diarrhœa	2	1	3
Cancer of stomach	1	..	1
Suicide	1	.	1
Obscure	.	1	1
	37	25	62

Under the head of epileptic convulsions I have classed cases in which death resulted as the immediate effect of a single convulsion, or a small number separated by considerable intervals; under that of status epilepticus those in which it followed a series of convulsions with little or no interval between them. In two cases acute œdema of the lungs supervened immediately upon a convulsion, and proved fatal within a few hours. These three categories embrace 38 cases, or more than three-fifths of the whole number of deaths. In addition to these, there is a class of cases, of which I have seen several examples, in which, with profound dementia, there is a gradual physical failure without evidence of any distinct disease other than epilepsy. This condition proved fatal in 7 cases, which should, in my opinion, be considered deaths from epilepsy, bringing the number up to 45, or nearly three-fourths of the whole. The remaining 17 deaths from other diseases would give a death-rate, on the whole number of epileptics treated, of only 7.27 per cent. The mortality from epilepsy is 19.23 per cent., a greater proportionate number of deaths from epilepsy than occurs in the general population of the Asylum—including as it does large numbers of patients suffering from general paresis and other forms of organic cerebral disease—from all causes combined.

Further confirmation of the tendency of epilepsy to shorten life is found in the ages attained by epileptic patients while under treatment, as shown in the following table:

TABLE III.—*Showing Ages attained by 234 Epileptics while in the Asylum.*

	ischarged.		Died.		Remain.		Totals.	
	Males.	Females.	Males.	Females.	Males.	Females.	Males.	Females.
Under ten years	..	1		1		.	..	2
Ten to fifteen years	4	5	2		..		6	5
Fifteen to twenty years	6	7	2	4	1	2	9	13

Sixty to seventy years	..	..	1	1	1	.	2	1
Seventy years and over	..	..	1	..	.	1	1	1
Unknown	1	..	..	..		.	1	..
Total	58	52	37	25	40	22	135	99

Only 36, or 15.4 per cent. of the whole number of epileptics treated, attained the age of forty-five years, during their residence in the Asylum. Of the 62 who died, fifteen, or not quite twenty-five per cent., had reached that age; while of 100 consecutive deaths of non-epileptic patients, 69 were of persons more than forty-five years of age.

A considerable number of the epileptics, included in the above tables as discharged, are known to have died elsewhere from the effects of their disease.

In the Eastern Michigan Asylum, at Pontiac, there had been, up to the date of publication of the last report, in October, 1886, 117 admissions of epileptics, of whom 34 had died. Of these deaths 16 were from epileptic convulsions, and 6 from status epilepticus. The total number of admissions up to the above date was 1,884, and the total number of deaths 280. While 14.9 per cent. of all patients admitted died from all causes, 18.8 per cent. of the epileptics admitted died of epilepsy.

In order to determine whether the experience of the Michigan asylums is singular in this respect, I have examined the reports for 1886 of fifty-four asylums for the insane in the United States and Canada, being all which have thus far been received here, the statistics of which are given in such form as to be available for the purposes of this inquiry. Of these, fifteen give statistics for their entire periods of operation. The following table shows the general mortality and the mortality from epilepsy in these institutions:

TABLE IV.—*Showing Number of Patients treated, and dying from all Causes, and Number of Epileptics treated, and of Deaths from Epilepsy in Fifteen Asylums for the Insane.*

Institution.	Total number of patients.	Total number of deaths.	Total number of epileptics.	Deaths from epilepsy.
Connecticut Hospital, Middletown	3,765	706	162	29
Willard, N. Y., Asylum	3,964	1,307	357	113
Asylum for Insane Criminals, Auburn, N. Y.	851	87	13	4
Warren, Pa., State Hospital	1,365	236	70	18
Danville, Pa., State Hospital	2,508	357	137	35
Central Asylum, Richmond, Va	1,691	433	100	28
Eastern Asylum, Williamsburg, Va.	1,499	491	107	46
Cleveland, O., Asylum	6,281	658	72	16
Dayton, O., Asylum	5,972	897	133	50
Longview Asylum, Carthage, O	5,518	1,226	259	86
Mendota, Wis., State Hospital	4,364	594	87	38
St. Louis, Mo., Asylum	3,197	369	152	17
Minnesota Hospital	4,129	693	206	80
Second Minnesota Hospital, Rochester	1,202	165	79	24
Provincial Hospital, St. John, N. B.	1,531	346	95	27
Totals	47,819	8,565	2,029	611

The mortality from epilepsy shown by these tables is much larger than in the Michigan asylums. The deaths from all causes are 17.91 per cent. of the total number of admissions, and the deaths from epilepsy are 30.11 per cent. of the number of epileptics admitted. The actual death-rate is doubtless somewhat larger, as a considerable number of patients have been admitted and counted several times. On the other hand, it is likely that a careful analysis would show that some cases of general paresis, cerebral tumor, and other organic cerebral diseases have contributed to swell the death-rate attributed to epilepsy.

The remaining thirty-seven institutions furnish, with the exception of a few biennial reports, available statistics for only a single year. They report, during that time, a total of 11,515 admissions, and 1,992 deaths. Of the admissions, 525 are classified as epileptics, and epilepsy is stated to have been the cause of death in 143 cases. Only four of the thirty-seven institutions fail to report deaths from epilepsy. The similarity between these figures and those obtained from the other set of reports is striking; the percentage of deaths to admissions being 17.3, and that of deaths from epilepsy to admissions of epileptics, 27.2.

It would not be difficult to collect additional statistics from similar sources; but, in view of the great uniformity of those given above, it hardly seems probable that they would materially modify the conclusions to be drawn. Making all due allowance for errors of diagnosis, it is evident that, in asylums for the insane, epileptic patients are more likely to die from epilepsy than from all other causes put together. Of course, the figures here given do not represent the real mortality. Of those discharged, or remaining under treatment at the time the statistics were made out, many, doubtless, ultimately succumb to the disease, and of those dying from other causes a large proportion would doubtless share the same fate if not prematurely cut off by some intercurrent disorder.

The question remains, To what extent conclusions drawn from the population of asylums for the insane are applicable to those who are not inmates of such institutions? Is there anything either in the character of the cases or their surroundings that would affect unfavorably their chances for life as compared with other sufferers from the same disease?

It is probably true that, as a class, the subjects of my tables were cases of more than average severity, although, so far as they have come under my personal observation, this has been by no means invariably the case. On the other hand, the epileptic inmates of such institutions are probably, on the whole, more favorably situated, so far as medical treatment and security against accidents are concerned, than those who are inmates of poor-houses, or the majority of those who are living at large. Such patients, if left to themselves, are very generally unwilling to follow out a consistent and thorough course of medical treatment. If benefited, they become impatient of the necessary restrictions; if, as is apt to be the case, the treatment is not very successful, they become discouraged, and either give up all effort to combat their disease, or, more commonly, become the prey of quacks. On the whole, it seems to me probable that the above figures represent pretty fairly the facts in regard to cases of considerable severity. When convulsions occur at long intervals, and but little disturbance of the cerebral functions results, the danger of a fatal issue is doubtless much less.

If several hundred cases of epilepsy, as they occur in the community, could be followed up, and the ultimate result of each one determined, such statistics would be much more valuable than any drawn from the inmates of public institutions. Their collection would, for obvious reasons, be a work of great difficulty.

It is not the purpose of this article to describe the mode of death from epilepsy. Leszinsky ("Epilepsy Considered as a Cause of Death," *New York Medical Journal*, vol. xli., p. 321) has given full reports of a series of cases which may be considered fairly representative. It may not be amiss to mention that in this institution chloral hydrate in full doses, administered by the rectum, if the patient is unable to swallow, has proved very efficacious in arresting convulsions in the status epilepticus, and in allied conditions, in cases of general paresis and of gross organic disease of the brain, and in not a few instances, has seemed to be the means of saving or prolonging life.

THE HEALTH OF LAS VEGAS, N. M.

By FRANCIS H. ATKINS, M.D.,

LAS VEGAS, N. M.

THE peculiar character of the death-record of the town of Las Vegas, in Northern New Mexico, as exhibited in the past year, is sufficiently striking to be worthy of publication and discussion.

The town lies at an altitude of 6,400 feet, and is placed snugly against the foot-hills of the Rocky Mountains and facing the mesa or great elevated plain extending eastward. It is on the main line of the Atchison, Topeka & Santa Fé Railroad, and is probably the most prosperous and promising town in the Territory. The underlying rocks are red and yellow sandstone and blue limestone.

The town contains about 6,000 people, fairly divided between 3,000 Mexicans and 3,000 Americans, for the most part living in separate portions; the former using adobe houses, and living—except as to a few better-class families—with utter disregard to all sanitary laws; the latter occupying mostly frame houses, and being a mixture of people from all parts of the United States, most of them having come here since the railroad was built in 1879.

As large numbers of consumptives come to New Mexico seeking health, deaths from phthisis frequently occur, but all deaths of this non-resident class I will omit, and also all deaths occurring among the Mexicans, as my wish is to study the effect of the climate upon the health of resident Americans.

The number of deaths was very small in the first four months of 1887, but I began my scrutiny, on which these notes are based, May 1, 1887.

Among the 3,000 Americans the following deaths were observed:

In May one man was hung by process of law, and he a non-resident.

In June a feeble infant, aged four months, died of scarlet fever, which its family, emigrants from Texas, brought to town with them in their wagon one week before.

In July a youth died after an operation for strangulated hernia; an infant, aged twelve days, died of marasmus; an infant, aged twenty months, died of cholera infantum.

In August an infant, aged two months, died of inherited syphilis; an infant, aged eleven months, died of cholera infantum (the family new-comers).

In September an infant, aged eighteen months, died of cholera infantum, having been brought here from Kansas City a week before, ill with the same disease.

In October a lady, aged twenty-six, a stranger visiting here for pulmonary disease, died of typhoid fever, of which a few cases then existed in town, hers being the only fatal case that year; an old and decrepit drunkard lay out all one stormy night and was found dead next morning; a syphilitic strumpet found dead in her room, body decomposed, was last seen after a furious fight with another woman in which she was badly used; a tramp, strictly non-resident, riding into town on the trucks under a passenger car fell under the wheels.

Between October 25, 1887, and January 24, 1888, a period of ninety days, no death occurred in Las Vegas, and then an old man, said to be broken by drink, poor and friendless, varied the agreeable monotony by dying. The preponderance of the newly come or non-resident element in this list is striking; also the small number of deaths from disease innocently acquired. It is perhaps only what might have been expected, that most of them occurred among obscure families in humble circumstances. When it is remembered that many of our families came here originally on account of the depressed health of one or more members, among whom, as not being very robust, deaths would be often expected if they lived at the East, I think this showing speaks remarkably strongly for the climate of Las Vegas.

That the death-rate is as low as this every year is not true, but it is probable that there are few if any places east of the great plains where it ever falls as low.

In 1886 the rate was considerably higher, 12 per 1,000 for the permanent American population, the chief though not only factor in that year's increase being typhoid fever, a disease that occurs occasionally in New Mexico, but has no frequency here above other countries.

In the same year the Mexican death-rate was $20\frac{2}{3}$, one-third of the dead being under two years, and one-third were over fifty years. The Mexicans are fatalists, and take little or no care to avoid disease. I have seen a dozen or more adults sitting on the floor about the edge of a room in the centre of which lay, on the floor also, a man in the last hours of fatal small-pox, while in the next room, the door between being open, were six or eight unvaccinated children playing. Even the Mescolero Indians at the neighboring agency had more sense, and both sought vaccination and avoided exposure to small-pox.

The most noteworthy fact about our American death-rate in 1886 is that no person, as far as could be learned, died of any pulmonary affection.

The climate of Las Vegas is much of the mountain-type, though less so than that of Santa Fé, and, because it is farther from the main range, less so, I believe, than that of Colorado Springs. I do not see that our climate can claim to be equable, nor do I know any part of the United States (and I have been in many parts) that can claim equability, unless parts of Florida and Southern California, and these lose by their dampness more than they gain by evenness.

The air here is very dry throughout nine months of the year, and by its rarity is tonic and stimulating; it does not differ, in fact, from that of Colorado, which is so much better known at the East, except in being milder, as it is farther south. Eastern people, even intelligent physicians, seem to associate the word "Mexico" in our Territory's name with heat, and sometimes refer to our climate as hot and debilitating, while the fact is that our various altitudes and latitudes give us a great variety of climates as to temperature and atmospheric tenuity, but all are alike in dryness.

Those who have wintered in Las Vegas will not readily believe that the mean temperature for winter in this part of New Mexico is about that of New York Harbor, St. Louis, and Salt Lake City, while the fact that records for several years show the summer mean to be about that of Detroit and Chicago will scarcely be appreciated by those who have spent a summer here, for our summer appears vastly cooler than that of Chicago, and sunstrokes are entirely unknown. The thermometer in this town rarely reaches 90° F.; but once last summer for an hour in July.

The winters are much milder than the mean for New York would suggest, the air being dry, the sun bright, children playing in the open air on most days without wraps, and mechanics working in their shirt-sleeves. On the other hand, strangers wintering here are surprised to find the mercury falling to zero or below. The winter of 1885–86 was unusually severe all over the United States, and New Mexico felt it with the East and South, though it had not been so cold here for over twenty years. In that January there was one week in which the mercury was below zero each morning, the lowest being 16° below; in 1886–87 the lowest I observed, with a standard thermometer, was 9° below; and the same during the past winter, with but a single other day when it reached zero. When the altitude and moderate proximity to snow-clad ranges 12,000 feet above sea-level are considered, these temperatures do not seem extraordinary. They are isolated, and serve to throw in stronger light the many weeks of mild dry days that each winter offers. At lower altitudes all over the Territory warmer winter weather can be found, but, except the most debilitated cases of consumption, there is rarely any invalid here who needs to seek other climate than that of Las Vegas.

In this region, in a total annual rainfall of 20 inches, fifty per cent. falls in July and August, and only eight per cent., or about $1\frac{3}{4}$ inch, in winter—all as snow, which rarely lies more than a few days—while the larger part of the remaining percentage occurs in September, with a stray storm in April. The skies are habitually clear and the sunshine fine; about two hundred and eighty days each year are observed as clear and fair. August is the most cloudy month. In some observations made near here, covering about three hundred days in two consecutive years, taken at random, and embracing the cooler months, November to March inclusive, only 48 days were noted as cloudy, on no day did any rain fall, on 13 days there was snow, yielding $7\frac{1}{4}$ inches of water. Similar observations for the same months and years, at St. Louis, Mo., gave 171 cloudy days, rain on 45 days, snow on 19 days, with a total precipitation of 32 inches of water!

The only unpleasant feature of the New Mexico climate it shares with Colorado and other Rocky Mountain regions; I refer to the high winds. These are usually limited to the first four months of the year, and in some years are almost entirely absent, as, for instance, from May, 1884, to November, 1885. These winds are not cold, rarely occur when the mercury marks the freezing point of water, and are very dry. It is a rare thing to hear visiting invalids complain of the winds, their attention being favorably bent upon the accompanying sunshine and dryness, and the contrast with the rain, slowly melting snow, and penetrating cold they have left at their eastern homes.

An outline of my professional duties during the December and January just past, may serve to show the nature of a physician's work in Las Vegas, and partly answer the frequent and embarrassing question, "What are your prevailing diseases?" Each title indicates the number of persons attended. Lithæmia, 2; chronic cystitis (Mex.), 1; phthisis (non-residents), 13; phthisis (resident), 1; pleurisy, 2 (both contracted at the East); anæmia and constipation, 2; menstrual disorder, 2 (1 non-resident); boil, 1; contusion, 1; vaccinations, 8; sore throats, 8 (mostly in children during high winds late in December, mild pharyngitis; all very slight, and generally calling for but a single visit); bronchitis, 5, all of the mildest catarrhal type, and rarely calling for a second visit; operation about knee (Mex.), 1; precautionary prescriptions for a pregnant woman about to go a journey, 1; life insurance examinations, 2; rötheln, 1; eczema, 1; colic, 2; erysipelas, 1; felon, 1; venereal, 2; conjunctivitis, 1; lacerated wound, 1; chilblains, 1; examination of chest in a healthy man by request, 1; stone in bladder, 1; thoracic aneurism, 1; lesion of aortic valves and of brain, 1; hysteria, 1. Of these, the only cases other than those of phthisis exciting any degree of professional anxiety, as endangering life, were the four last named in this list, all being non-residents.

Having already referred to the rarity of pulmonary diseases, I will also state that, in eight years' residence in New Mexico, I have seen no cases of degeneration of the kidneys, as shown by albuminuria, dropsy, etc., except in scarlet fever, and I have seen no acute rheumatism. In other words, Bright's disease and acute articular rheumatism are practically unknown, and I should suppose this climate to be as valuable for cases of incipient renal disease as it is for early lung degeneration.

Pleurisy must be an exceedingly rare disease in this Territory, for I have seen but two cases of it, and both of these were brought from the Eastern States. I have never seen a case of catarrhal pneumonia. Bronchitis is usually very light, of a mild catarrhal type; I never saw a severe case. Asthma does not originate here, and cases visiting us secure prompt relief. Debilitated children brought here speedily improve, and incipient consumption disappears.

I recall but three cases of consumption developing among residents under my notice. One was a Mexican woman who had been everybody's temporary wife; one was a young and very delicate girl, I believe of bad family history, but a year or two here, who succumbed to acute phthisis induced by scanty food; and a woman from New York State, of a highly consumptive family, who came here twenty years ago, and developed phthisis, after a pneumonia, ten years ago, but she still leads a very active life and works hard. Two of these, it will be seen, brought the seeds of the malady with them.

It is a common remark among Americans who have lived here fifteen or twenty years, that they never heard of a case of consumption among the Mexicans; but closer professional scrutiny shows that very rarely a case does occur.

Our towns and ranches are full of people who have secured a suspension of the destructive processes in phthisical lungs, and are filling the ordinary duties of life. Such cases occasionally sustain a relapse, but it is wonderful to observe how quickly the fever is broken and the restorative processes reinstated by the aid of a little medical treatment.

It is generally useless to send to New Mexico cases of phthisis that are far advanced in lung destruction; Florida or San Diego will insure them a more certain euthanasia. Such cases find that the rare air increases their dyspnœa and general weakness and distress. But where the extent of lung involved is small, and the patients are still able to follow a rather active out-door life, this country will save them if anything can. Still, on the other hand, we occasionally see the disease arrested in cases where much lung space is involved, and the patient apparently hastening to death, but not enough of such to justify us in urging them to come, as we do the class with less disease.

It may be remarked that children's diseases are quite rare among Americans in these higher altitudes, and that the few deaths from cholera infantum mentioned above would be a very large number for any year in Las Vegas.

The substance of these notes was presented to the New Mexico Medical Society, at a recent meeting, and, at the request of the Society, have been elaborated and forwarded for publication.

Fashions for the Dead.—James Hodge continues to sell burying-crapes ready made; and his wife's niece dresses dead corpses at as cheap a rate as was formerly done by her aunt, having not only been educated by her, but perfected in Edinburgh, from whence she is lately arrived, with all the newest and best fashions for the dead. —*Glasgow paper.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, April 28, 1888.

THE SIGNIFICANCE OF HYDROCHLORIC ACID IN THE DIAGNOSIS OF GASTRIC DISORDERS.

OF late years great changes, we were about to say advances, have taken place in the methods employed in the diagnoses of diseases of the stomach. Much less importance, relatively, is attached to the results of palpation and percussion, and to the subjective symptoms of the patient, and more reliance is placed upon the chemical tests of the gastric secretions. Many clinicians have come to regard the presence or absence of free hydrochloric acid as a symptom of very great importance, especially in the diagnosis of carcinoma, yet it is by no means certain that this sign is as reliable as some would have us believe.

The Paris Academy of Medicine devoted the greater part of two meetings, those of January 17th and 24th, to the discussion of this subject. M. Germain Sée read a paper in which he described a new test for hydrochloric acid, recently proposed by Dr. Günzburg, of Frankfort. Two grams of phloroglucine and one gram of vanilline are dissolved in thirty grams of absolute alcohol, forming a solution of a brownish-yellow color. One drop of this solution, in the presence of a very minute quantity of a concentrated mineral acid, assumes a bright-red color and deposits beautiful red crystals, but no change takes place with the organic acids, such as lactic or acetic, or even with the chlorides mixed with these acids. No visible reaction occurs with dilute mineral acids, but, upon evaporating such a mixture in a porcelain dish, the last few drops assume the red color. In testing the gastric secretions, a few drops of the filtered liquid are mixed with an equal quantity of the solution of phloroglucine-vanilline, and evaporated carefully. A reddish residue, containing the characteristic crystals, is left in the dish. This test is sufficiently delicate to show the presence of hydrochloric acid even in the minute proportion of 1 part in 10,000. When the gastric fluid contains a quantity of albuminates or peptones the crystals are not formed, but the red color persists.

M. Sée then discussed the question of the diagnosis of gastric disorders based upon the presence in excess or the absence of free hydrochloric acid. In cancer the absence of this acid was regarded by many as pathognomonic, but though this was the almost invariable rule it was not without its exceptions. Carcinoma is not, however, the only affection in which the most careful tests fail to reveal the presence of hydrochloric acid. In the later stages of catarrhal gastritis, the speaker said, after atrophy of the glands and other interstitial changes have taken place, it becomes impossible to demonstrate the presence of this acid. In dyspepsia occurring in tuberculous and uræmic subjects there is also often a persistent absence of hydrochloric acid.

Hyperacidity of the gastric secretions, he stated, is of very frequent occurrence, an excess of hydrochloric acid having been found by Boas in 120 out of 200 cases of dyspepsia examined by him. The exact conditions in which this hyperacidity exists have not yet been determined, although it is known that it is present very frequently in gastric ulcer.

M. Dujardin-Beaumetz thought that too much importance had been attached to changes in the gastric secretion as a diagnostic sign in diseases of the stomach, especially by the German school. Ewald and others had been led to assert that the absence of free hydrochloric acid in the stomach was pathognomonic of cancer, but such an opinion could no longer be entertained, since it had been proven that the acid might be absent in a number of other affections. In many cases of dilatation and of dyspepsia occurring in tuberculosis and other cachectic conditions the most careful tests, frequently repeated, had failed to detect the presence of this acid at any time. And, on the other hand, free hydrochloric acid had been found constantly present, even up to death, in cases which were shown at the autopsy to be carcinoma. The speaker thought that the examination of the gastric secretions should always be made, when possible, and he believed that, taken in connection with the other symptoms, the results of such an examination might afford valuable evidence of the nature of the lesions present, but they should never be relied upon to the exclusion of other equally valuable diagnostic indications.

THE ACTION OF DRUGS AT A DISTANCE.

THE study of hypnotism and the conditions allied thereto has become so far advanced in France that all eyes have been turned in that direction to see what the possible outcome of the craze will be. Fortunately the phlegmatic German is also taking some interest in this subject, and whatever result he may reach it will certainly be exact, and free from all unnecessary enthusiasm.

One part of this latest fad is the action of drugs at a distance, and the zeal with which M. Luys has pursued this subject is worthy of that of a monomaniac.

In 1887 M. Luys, in repeating the experiments of MM. Burot and Bourru (of Rochefort) confirmed them. He then attempted to show that drugs placed at a distance, or in contact with subjects in a state of hypnotism, would provoke certain symptoms, and in particular emotional symptoms, varying with the drug used. In closing his communication on this subject he called attention to the consequences which could result from such experiments. They opened, in his opinion, a new way to therapeutics, and, from a medico-legal point of view, these experiments could be of interest as modifying or reversing the action of certain drugs, and causing death without leaving a trace. This statement produced such a profound impression that a commission was charged with the task of investigating this further. M. Dujardin-Beaumetz and four others constituted this commission, whose first duty was to fix the limits of its work and research. It let alone all questions of hypnotism except the one in question, and undertook the following programme :

In the first séance M. Luys was to reproduce his experiments as he usually did, and then in the remaining experiments he was to renew these experiments in an especial way, which the commission arranged. Then, in these experiments, to avoid error, it was important that neither the subject in use, the experimenter, nor the members of the commission should know what substance was used. The preparation of the substance was to be left to a stranger to the commission and experimenter, and a proper and reliable man, a pharmacist, was selected. He followed Luys' plan of using sealed glass tubes. He took the commission sixteen tubes, ten of which were closed, and, like those of M. Luys, contained a solution. One was exactly like the other, so that the sharpest examination could detect no difference. Six other tubes contained substances in powder, which was in a paper inside of the bottle, and, to hide the contents, each bottle was numbered so that at a glance its contents could be made known. An empty tube was also used.

M. Luys selected a subject which, in his opinion, was best fitted for this experiment, and placed her in a proper condition ; then one of the commission took any one of the tubes, without selecting it, and noted with great care the symptoms called forth by the tube. M. Luys claimed that he obtained with the same drugs essentially similar results. In order to make the test more complete, the commission decided that the numbers on the tubes should be changed. In the first séance M. Luys took a young girl and put her through the three different phases of hypnotism ; the lethargic, the cataleptic, and the somnambulistic stages. He then took the subject in the lethargic stage, in which there was the appearance of a neuro-muscular hyperexcitability, especially in certain regions, as in the anterior brachial region, where simply blowing on the skin caused contractions. In this period he used the drug, and by holding these sealed tubes containing drugs behind, at the side, or in front of the head, he produced certain well-marked symptoms characteristic of the drugs themselves when taken. There was a period of exaltation, a period of rest, and a period of decline, and this was repeated in the reverse order. In all his experiments the tubes bore labels. These tubes were presented to the one side and the other, to the organs of sense and those behind the neck. Among the drugs used were the sulphate of sparteine, essence of thyme, ipecac., haschisch, pilocarpine, etc. The commission then repeated the experiment, using their tubes and also the empty tube, and, after careful study, they came to the conclusion that the whole thing was destitute of scientific basis, although they believed that M. Luys had good intentions. The effect seemed to depend more on the caprice, fancy, and memory of the subject, than on the substance in the tube. The commission was decidedly of the opinion that the effect was in no way like the normal effect of those drugs, and that the result was in no way of interest to therapeutics. This decision by the Academy should have a quenching effect on this subject ; but anyone who has seen M. Luys work will feel certain that he will not so easily be convinced of his wrong. The search for proper subjects will be limited to a few of the weaker sex.

A NEW METHOD OF DISPOSING OF THE DEAD.

A STARTLING proposition comes from a Pittsburg chemist as to the disposal of the dead. It bears intrinsic evidence as coming from a man of an economical turn of mind, who is profoundly impressed with the doctrine of the conservation of energy. The prime idea is to pulverize the body with the aid of machinery. The bones are first to be broken into pieces of the size of an egg ; then into smaller fragments, and so on, and the mass thus produced is to be passed through a mincing machine. "At this stage," says the originator of the plan, "we have a homogeneous mixture of the entire body in the form of a pulpous mass of raw meat and raw bones." We do not desire to shock the sensibilities of our readers, but we give the facts just as they are.

This "cheese," as the cider-makers would call it, should be thoroughly dried by superheated steam and subjected to pressure—thus disinfecting and condensing it. It can then be used for fertilizing purposes.

A second plan proposed is by boiling in close vessels, with the removal of the fatty products. The remaining mass can then be heated as before.

But the third method is the most startling and original. The bodies are to be placed in gas-retorts and converted into illuminating gas, water, ammonia, tar, and animal charcoal. Subsequent distillation will yield aniline colors, carbolic acid, and ammonia sulphate. It may be suggested that a new antipyretic alkaloid is among the possibilities.

Such proposals excite only derision, and may be condemned by many as a jest on a solemn subject. Yet they show the tendency of the times to turn from the merely sentimental to the practical and sanitary view of the disposal of the dead. Cremation as now practised is on the gain. It may soon become adopted by the city instead of the present burial in the "Potter's Field," which is rapidly filling up. It is already used, with perfectly satisfactory results, in one of the medical colleges here to dispose of the refuse material from the dissecting room.

THE LESSON OF A LIFE.

THERE have been few physicians whose death has caused so wide-spread and sincere grief as has that of Dr. Agnew. This was due, we take it, largely not so much to his professional eminence as to the exceptional purity and elevation of his character. Dr. Agnew was a Christian gentleman in the best sense of the word ; devout without bigotry, sincere and earnest without pretence or intolerance. He impressed those whom he met as singularly free from pettiness of spirit, jealousy, or ignoble prejudices. Generous and liberal toward those with whom he disagreed, no personal attacks ever seemed to crown his anger or call out vindictiveness. He lived in a region quite above the smaller passions that consume so many.

His was the kind of spirit which we should be glad to see more widely diffused, not only in our profession, but everywhere. The liberality of mind, the wide and generous interest in everything that would help his fellow-man, were distinguishing traits in the character of the late Dr. Agnew. We can only hope that they will be remembered and imitated.

News of the Week.

A COMPLIMENTARY DINNER TO THE SURGEONS-GENERAL OF THE ARMY AND NAVY.—On Saturday evening last the Practitioners' Society of New York tendered a complimentary dinner to the Surgeons-General of the Army and Navy at the University Club, in this city.

The occasion was one which afforded opportunities for the cultivation of those professional and social relations which tend to the ultimate good of all concerned. Besides the members of the Society and the distinguished gentlemen in honor of whom the dinner was given, there were several invited guests, consisting of the members of the Medical Corps of the Army and Navy on duty in this city. The President of the Society, Dr. Shrady, welcomed the guests in the name of the Society and on behalf of the profession of this city.

Surgeon-General John Moore responded for the Army, giving an interesting and comprehensive survey of the past and present working capacities of the corps, and concluding with a touching tribute to the bravery and devotion to duty of the surgeon on the battle-field. Surgeon-General John M. Browne, of the Navy, followed with some telling personal experiences in the different grades of his medical service, and alluded in eloquent terms to many of his old comrades. He concluded by asking the members to suggest some means by which the vacancies in the Navy Medical Department might be more speedily filled. Both addresses were received with warm applause.

After a few humorous remarks by Mr. St. Clair McKelway, of Brooklyn, the remainder of the evening was spent in an informal and conversational manner, much to the enjoyment of all. Among those present were: Drs. Samuel Sexton, James B. Hunter, A. H. Smith, R. F. Weir, W. T. Bull, C. Cleveland, C. L. Dana, A. A. Smith, V. P. Gibney, F. P. Kinnicutt, J. W. Roosevelt, J. E. Pilcher, U.S.A., and the following gentlemen of the Navy: Drs. Delavan Bloodgood, N. L. Bates, J. R. Tryon, George Peck, and E. I. Bogert.

THE CHRISTIAN SCIENTIST'S THEORY OF CONSUMPTION.—A lady mind-curer, in a lecture before the Nineteenth Century Club, recently said: "Consumption—so far as I have been able to trace it—has its basis in homesickness—longing for the home-ties. It repeats itself through fear of and belief in it. *Fear always indicates a vacuum.* The correspondence between the form of disease and the thought is so well established that, tell me an individual's diseases and, in nine cases out of ten, I will approximate closely to his thought-experiences." In explaining why the "mind-cure" does not prevent poisoning by strychnia, she said: "We recognize the fact that no man stands alone. You are a part of me. Until your thought reaches a point at one with my thought I am bound by you. As long as you hold to the belief that strychnia is poison, how am I going to be strong enough to overcome it?" All this goes to show what arrant nonsense is talked when the mind-curer tries to theorize.

SIR MORELL MACKENZIE AND MR. HOVELL have brought an action for libel against the Cologne *Gazette* and the *Kreuz Zeitung* for publishing an account of an alleged incident in connection with the Emperor's illness on the 11th inst. These papers published sensational items of news stating that the Emperor was almost throttled owing to the clumsy treatment of Drs. Mackenzie and Hovell in placing the rectangular cannula in his throat, and that Dr. Mackenzie had to send for Dr. Bergmann, who was only just in time.

MOUNT SINAI HOSPITAL, NEW YORK.—A vacancy exists in the Department of Internal Diseases (out-door staff) of this hospital. Applications for the position can be forwarded to De Witt J. Seligman, Honorary Secretary.

OUR PHILADELPHIA BRETHREN are certainly losing their reputation for brotherly love, for even at the banquet recently tendered to Dr. D. Hayes Agnew there seems to have been some lack of harmony. One esteemed contemporary prints in full an ode to Professor D. Hayes Agnew, by Dr. Thomas Wistar. This we have read with pleasure, for it shows poetic feeling and much literary skill. Another contemporary, however, prints only a poem by Dr. Weir Mitchell, and quite ignores the ode, which we must candidly confess to be the better literary work of the two. Between the readings of the two poems, according to the *Medical Register*, a motion to adjourn was made; from which we infer that the banquet was conducted under parliamentary rules.

BAD MORTALITY-RATES AT MATERNITY HOSPITALS.—The City of London Lying-in Hospital has a mortality-rate of 22.1 per 1,000. Such a percentage in a lying-in hospital should always call for an investigation.

A CASE OF ANTHRAX.—A workman in a leather-establishment in this city has recently died of malignant œdema, or anthrax. He contracted the disease undoubtedly from handling hides. The patient was treated in Chambers Street Hospital, and the anthrax bacilli were found in the blood.

THE URETHRA A RIFLED PASSAGE.—Mr. W. W. Wagstaffe has found by experiment that the normal urethra is rifled somewhat after the manner of a gun-barrel. The spiral runs from left to right in about the upper three-fourths of its extent, but then usually becomes reversed. The twist is sufficient to turn a bougie half-way around, *i.e.*, about 180°. It is suggested that the spiral arrangement is to secure, as in the gun, greater precision in the direction of aim! Truly, modern science is constantly revealing fresh wonders of creation.

HAMMER-TOE is being the subject of much controversy by English surgeons. Some consider it due to badly fitting boots, others think heredity an important factor. All agree that it is easily cured by division of ligaments.

FAME.—Professor Martin, of Johns Hopkins University, is a widely known physiologist and author. Yet we find the following in a Philadelphia contemporary: "They have a Dr. H. N. Martin at Johns Hopkins University. Bet he can't prescribe equal to ours."

MORTALITY FROM LARYNGECTOMY.—Some days ago Herr Kayser, member of the Social Democratic section of the Reichstag, died immediately after a partial extirpation of the larynx for cancer, which was performed by Professor von Bergmann, our leading surgeon. A like result followed the last two operations of the same kind done by Dr. E. Hahn, who is well known in England for having operated on Mr. Montagu Williams. It is also said, but I cannot vouch for the truth of the statement, that all the eleven other patients on whom Professor von Bergmann has performed laryngectomy have died.—*Berlin Cor. Brit. Med. Journal.*

THE MEDICAL INVESTIGATOR is the title of a new journal devoted to medicine and temperance, edited by Dr. S. F. Smith, and published by him at Louisville, Ky. Dr. Smith will editorially affirm: "1. That alcohol is a poison. 2. That it is a morbific agent. 3. That inebriety is a disease. 4. That State and National governments should prohibit the retail liquor traffic as a sanitary measure." The editor states that he wants one hundred thousand subscribers, and we trust he will get them.

THE NURSING RECORD is the title of a new weekly journal published in London in the interest of nurses and nursing.

GOLD FOR ANÆMIA.—The blond races of Northern Europe, when suffering from anæmia, are helped more by the salts of gold than by those of iron, according to M. J. Roussel.

CONIUM IN RECTAL PAINS.—The succus conii, made up as an ointment, gives great relief in rectal neuralgias, pruritus, and painful fissures, etc., according to Dr. W. Whitle, in *The Practitioner.*

CANCER TREATED BY INOCULATION OF ERYSIPELAS.—Drs. Busch and Fehleisen some time ago deliberately exposed cancerous patients to erysipelas, in order to get a supposed curative action from the erysipelatous inflammation. They showed that a peculiar streptococcus was pathogenic of erysipelas. Recently Dr. Axel Holst, of Christiana, inoculated a patient suffering from mammary cancer with erysipelas-virus. The resulting inflammation checked the cancerous growth for a few months, but it is doubted if it much prolonged the life of the patient.

THE LATE DR. C. R. AGNEW.—At a meeting of the New York Academy of Medicine, held April 19, 1888, the following preamble and resolutions were unanimously adopted, and, as a further mark of respect to the memory of Dr. Agnew, the Academy thereupon adjourned:

The New York Academy of Medicine has been informed of the death, on Wednesday, April 18, 1888, of Dr. Cornelius Rea Agnew, who, both as an officer and a member of the Academy, has been most assiduous and successful in his efforts for its welfare.

The Academy hereby records its appreciation of his untiring zeal, of his eminent ability, of his executive capacity, and of his fidelity; of the largeness of his views for its development, of his generosity, both in his gifts and in personal labors for its good.

He was alert to make the best of its methods of work, as well as to improve their efficiency. He sought to develop its scientific discussions and proceedings by judicious classification of subjects; he was warmly interested in the enlargement of the library; he was exacting in attention to economy in the expenditure of its funds; he was deeply earnest in the plan for procuring a new building. In his loss the Academy has sustained a heavy blow, and the removal of his friendly and energetic personality is a great bereavement, while we shall miss his wise counsels, his discriminating judgment, his courtesy and vigor in debate, and his promptness in forwarding every scheme for the scientific and practical advantage of the Academy. We have lost a true friend and an efficient worker.

Beyond what he has done for the Academy we are proud of his achievements in what makes the medical profession an honor and a power for good. He founded two eye and ear hospitals and placed them on a successful basis.

He aided in the organization, and was, for many years, one of the managers of an asylum for the insane. He was active in many medical societies. While practising a specialty, his outlook and concern were for the whole profession.

He had no professional narrowness and his judgments were always inclined to be charitable to those who differed with him. His services as a patriot are part of the history of our country, he was zealous for the civic weal, and a leader in movements for reform. Sanitary and social improvements were among the causes to which he earnestly devoted himself. He took an active part in helping on education, both in its popular cultivation and in its higher and technical developments.

Probity, uprightness, unselfishness, and courage were typified in him, while his character was imbued and moved by deep religious conviction.

His life is to us a glory and a stimulus.

Resolved, That we respectfully tender to his family the assurances of our deep sympathy, and with the tribute of our affection our high admiration for the many noble qualities which were embodied in Dr. Agnew.

ALFRED L. LOOMIS, M.D.,
WILLIAM H. DRAPER, M.D.,
HENRY D. NOYES, M.D.,
Committee.

A. JACOBI, M.D., *President.*
A. M. JACOBUS, M.D., *Recording Secretary.*

At the Stated Meeting of the Medical Society of the County of New York, held April 23, 1888, the death of Dr. C. R. Agnew having been announced by the President, on motion the regular business of the meeting was set aside until suitable action should be taken. Eulogistic remarks upon the deceased member were then made by Dr. D. B. St. John Roosa, who also offered the following resolutions:

Resolved, That the Medical Society of the County of New York, in the death of C. R. Agnew, M.D., LL.D., mourns the loss of one of its most distinguished members, who had by his professional achievements brought honor to his native city and country in every land where medical and surgical science are cultivated.

Resolved, That we bear our testimony to the justness and integrity of a life devoted to his fellows, and to the qualities which made him under the most trying circumstances that occur in the history of a medical organization one of our most trusted and wise counsellors.

Resolved, That the memory of his professional career will ever be to us an incentive in our endeavor to elevate and maintain the high standard of professional life and character, and that we mourn his loss as that of one of the leaders in uprightness and progress of medical affairs.

The resolutions were adopted unanimously.

At a meeting of the Board of Directors of the Manhattan Eye and Ear Hospital, held on April 19, 1888, the following resolutions were adopted and ordered to be placed upon the minutes of the board:

Resolved, That the death of Cornelius Rea Agnew, M.D., the Secretary of this board, a surgeon to this hospital, and one of its founders, is deplored by us as a great calamity to this charity, one that deprives us of a man possessed of remarkable medical and surgical knowledge and skill, combined with a rare kindliness of spirit and devotion to duty.

Resolved, That we mourn the loss of one distinguished in many arenas for executive ability and wisdom, which were here especially called into action in the successful establishment and maintenance of our hospital.

Resolved, That we shall ever cherish the memory of Doctor Agnew, as an incentive to the performance of our duties in the care of this institution, so largely a monument to his Christian philanthropy and professional achievements.

John Sinclair, M.D., *President.*
D. B. St. John Roosa, M.D., *Secretary pro tem.*

At a special meeting of the junior members of the medical staff of the Manhattan Eye and Ear Hospital, held on Friday, April 20, 1888, the following resolutions were adopted:

Whereas, It has pleased an all-wise Providence to remove from our midst, and the scene of his earthly labors, our friend and colleague Dr. Cornelius Rea Agnew;

Resolved, That each member of the junior staff of the Hospital feels the sad bereavement as a personal loss.

Resolved, That it may be safely said he was to each and every member, on all occasions, as an elder brother, as well as a counsellor and guide. His suavity of manner, and his kindly and lovable disposition, endeared him to each of his colleagues, as well as to all who were fortunate enough to be brought in contact with him.

Resolved, That his was a high type of manhood, true and noble in its every expression, and brimful of the warmest and tenderest sympathies for his poor and suffering fellow-man. He was a man of prodigious industry, and always on the alert to do. This Hospital is an outcome of that industry, and was called into existence largely by his indomitable pluck and energy. It will remain a lasting monument to him, the last but not the least of his life-work.

Resolved, That we tender to his wife and children our deepest and most heartfelt sympathies in this time of general sorrow, expressing at the same time the hope that He who "tempers the wind to the shorn lamb" may mitigate, to some extent at least, the poignancy of their grief.

Resolved, That a copy of these resolutions be engrossed and presented to his family.

George F. Carey, M.D.,
Charles G. Johnston, M.D.,
J. Oscroft Tansley, M.D.,
Committee.

Obituary.

EDWARD GREELY LORING, M.D.,

NEW YORK.

Dr. Edward G. Loring, the distinguished ophthalmologist of this city, died suddenly, April 23d. The deceased left his home on the afternoon of Monday, April 23d, in apparently the best of health, after telling Mrs. Loring that he was going to look at his pleasure-boat, which was moored in the East River somewhere in the neighborhood of Seventy-fourth Street. At six o'clock a policeman belonging to the Twenty-fifth Precinct noticed a gentleman fall on the sidewalk at the corner of Seventy-fourth Street and Park Avenue. The officer rushed to the assistance of the prostrate man, but he saw at once that life was extinct. The body was conveyed in an ambulance to the Sixty-seventh Street Station-house, and later in the evening, after having been identified as that of Dr. Loring, it was removed to the Madison Avenue residence.

For a day or two he had complained of a slight pain in the chest, but neither he nor his friends had attached any significance to it. On the day of his death, however, he was feeling perfectly well, and told his wife that he should be back to dinner soon after six o'clock. He was evidently hurrying home when he fell dead. Mrs. Loring grew anxious as the time passed and her husband did not return, and when a policeman from the station-house, who was sent to inform her of Dr. Loring's sudden death, reached the house, she was standing at the window watching for his coming. She was nearly prostrated by the shock of the bad news.

Dr. Edward Greely Loring was born in Boston in 1837. He was a son of Judge Edward Greely Loring, of the Court of Claims. At an early age he was sent abroad, and studied medicine in Italy, from whence he returned to the United States, and graduated in 1864 from the Harvard Medical School. Dr. Loring then started to practise medicine in Baltimore, where he remained for only one year, subsequently coming to New York, where he became a partner of the late Dr. Agnew. This association lasted six years. Subsequently to this he established an independent practice, which he actively and lucratively maintained up to his death. He had no professorship and had obtained his position and fame simply by private and personal work, and he had been spoken of as a fit successor of Dr. Agnew at the College of Physicians and Surgeons. He was one of the founders of the Manhattan Eye and Ear Hospital, and for many years was ophthalmic surgeon to the New York Eye and Ear Infirmary.

Dr. Loring was a profound scholar in his specialty, and was an authority even among his peers concerning the more abstruse and problematical questions connected with optics. His contributions to ophthalmology were of singular value, and it is a matter of sad regret that his intention of embodying the results of his life-study is so summarily frustrated, after the appearance last year of the first volume of his treatise on ophthalmoscopy.

Dr. Loring was a modest, studious, and untiring worker, was retired in his manners, earnest in his friendship, and was loved and respected by his many admirers and friends.

He was a member of the New York County Medical Society, as also of the Academy of Medicine, the New York Ophthalmic Society, the American Ophthalmic Society, and the Practitioners' Society of New York.

Dr. Loring married twice, his first wife being Miss Jarvis, of Florence, Italy. His widow's maiden name was Miss Swift, a niece of the late Judge Rapallo.

A Cure for Red Noses is given by a correspondent of the *British Medical Journal*, who was himself a sufferer. It consists in free scarification, at first twice a week, then less often.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 23, 1888.

Dr. Laurence Johnson, President, in the Chair.

The death of Dr. C. R. Agnew was announced and suitable resolutions offered (*vide* p. 474).

Dr. William C. Jarvis then read a paper on

THE INDICATIONS FOR THE SURGICAL TREATMENT OF THE DEFLECTED NASAL SEPTUM, WITH AN ANALYSIS OF ONE HUNDRED CASES.

There were, he said, definite symptoms and pathological complications which were easily recognized and explained as being more or less continuously associated with this disease, and which afforded excellent guides for its successful treatment.

He excluded from his one hundred cases those which occurred in public practice, and certain ones in private practice as of doubtful value, because of the omission of certain details.

Of the 100 cases of deflected nasal septum, 30 were deflected to the right and were cartilaginous in character; 40 purely cartilaginous deflections were to the left; 8 were bilateral deflections; 12 were osseo-cartilaginous deflected to the right; 5 to the left; only 3 were purely osseous deflections, 2 of which were bilateral.

Regarding the principal indications for surgical treatment, the first was nasal stenosis. This it was that usually brought the patient to the doctor for treatment. There was complete stenosis of the right nostril in 29 cases; of the left nostril in 20 cases; in 18 there was incomplete stenosis of the right nostril; of the left, in 14. Thus 81 of the cases had stenosis.

Among the most important complications which called for operation was turbinated hypertrophy. In 24 of the cases there was hypertrophy of the deflected septum thrown to the right; 8 of these cases required especial operation for removal of redundant tissue; in 20 deflected to the left, 4 required special operative procedure for removal of redundant tissue, the snare being employed for that purpose. Of posterior hypertrophies there were 6 occupying the right nostril, 2 of which demanded operative interference; 8 occupied the left nostril, 4 of which required an operation for their removal. He did not include slight redundancies which were seen in every case of deflected septum.

Of the 100 cases, in 29 there were marked ear symptoms. Eye complications were marked in 11 cases. There was well-marked catarrhal headache in 15; hay fever in 8; bronchitis in 7; polypi in 4. In 94 there was hypertrophic rhinitis; atrophic rhinitis in 2; fetid atrophic rhinitis in 4.

Nasal stenosis might be absolute or variable in character. When variable and causing snoring, it might reduce the health of the patient by causing him frequently to awake, and by causing irritation and inflammation of the lower air-passages.

Regarding the possibility of making errors in diagnosis, Dr. Jarvis expressed the opinion that in many cases the turbinated bones had been removed when the patient was suffering only from temporary congestion not associated with true stenosis. An erroneous diagnosis could be avoided by comparative observation, the use of cocaine, the use of the rhinometer, and the lapse of time.

In a large percentage of the cases the deflection acted like a dam, causing the secretions to accumulate within the nasal cavities. Here an operation should be made to restore the nasal gutter.

Cases in which an operation was not called for were as follows: Instances of extra-nasal deflection, occupying the vestibule, and not the cavity, of the nostril proper; cases in which the deviation of the septum was so far forward that the projecting cartilage only just met the anterior border of the turbinated tissues, the turbinated tissues having room to rise and fall without striking the septum; cases of deflected, non-obstructive septa; non-obstructive deviations in the nostril exhibiting a pale or normal hue of the pituitary membrane; cases of slight localized, non-obstructive bending of the vomer placed above the nasal gutter in the most spacious portion of the nostril; cases of deflected, non-obstructive septa having smooth and regular conformations and a gradual lateral incline.

In conclusion he said he was mindful of the fact that his cases did not include all the conditions growing out of deflection of the septum demanding an operation. He could not, on this occasion, discuss methods of operating and general treatment.

The paper was discussed by Drs. Bucklin, Rice, Phillips, Tansley, and Robinson.

Dr. Bucklin referred to a question once raised by Dr. Jacobi, as to how much space was required to permit of free breathing through the nostril, and said there should be sufficient room for free play of the mucous membrane covering the turbinated bones. This varied with changes of temperature, and in different individuals, and with the state of health. He thought it was more detrimental to the patient to be making efforts at breathing through nostrils which were alternately open and obstructed, than to have complete nasal stenosis. A young man had night-sweats, and active symptoms of phthisis; removal of nasal obstruction was followed by a gain of one pound in flesh weekly for several weeks.

Dr. Tansley said that while many cases of deflected septum might be accompanied by ear trouble, there were hundreds who had ear trouble who had no nasal stenosis. During the year he had seen but about five bent septa among his cases of aural difficulty. A number of patients had come to him with acute aural trouble following an operation upon the nose.

Dr. Jarvis advised the dry and open method of treating the wound after an operation on the nose. The wound healed more kindly, and there was less likely to be aural complication.

Dr. Charles H. Avery, Assistant Secretary, was elected Secretary to fill the unexpired term of Dr. Carpenter, deceased.

Thyroidic Leucocythæmia.—M. Hayem has related the case of a woman, aged sixty-two, in good health until the present illness began (*The Lancet*). Fourteen years ago, after her last confinement, a swelling of the right lobe of the thyroid gland was observed, which, however, remained stationary till last October, when it began rapidly to augment, until it became voluminous, displacing the œsophagus and trachea to the left, and causing difficulty in swallowing and attacks of impending suffocation. The carotid artery lay in front of the tumor, whose consistence was hard, and did not present a murmur. The cachectic aspect led to the blood-corpuscles being counted, and the discovery was made that, besides chronic anæmia, there existed a considerable augmentation—70,000 per cubic millimetre—of white blood-corpuscles. The liver was not enlarged, neither was the spleen nor any of the lymphatic glands. M. Hayem makes the inquiry whether this increase in the number of white blood-corpuscles should justify the employment of the term "thyroidic leucocythæmia." A certain degree of leucocytosis usually accompanies the growth of some malignant tumors, no matter what their situation, and the same kind of increase in white blood-corpuscles is observed in phthisis, empyema, and other inflammatory diseases, irrespectively of site; but the degree of leucocytosis in Hayem's case is much above the level usually found in such cases of leucocytosis.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 14, 1888.

W. P. Northrup, M.D., President, in the Chair.

Dr. Frank Ferguson presented a specimen of

ANEURISM OF THE ARCH OF THE AORTA,

which had ruptured through the pulmonary artery into the right ventricle. The person from whom the specimen was taken was past middle life, and had died soon after admission to St. Luke's Hospital. The only history obtainable was that of the patient having been troubled with shortness of breath for some time before his admission to the hospital. A peculiarity of the case was that one of the cusps of the pulmonary valve was found to be glued tightly to the wall of the pulmonary artery for a distance of about an inch.

Dr. Ferguson also showed an immense

COLLOID CARCINOMA OF THE PERITONEUM,

removed from the body of a man fifty-one years of age, who had been admitted to the New York Hospital during the service of Dr. Peabody, on July 30, 1887. For the past four years he had had repeated attacks of muscular rheumatism. He had never had malaria, syphilis, nor symptoms of any renal trouble except swelling of the feet, from which he had suffered continuously for a year. Three years before admission his abdomen began to swell, and he had a burning pain about his waist. He also experienced difficulty in urination, the urine being passed at first in a small stream, but finally, the bladder becoming over-distended, incontinence ensued. During this time the patient lost flesh and strength. Examination of the abdomen showed the presence of a large, firm, unyielding mass, tender on pressure, and also of a number of smaller tumors, situated apparently just beneath the abdominal wall. There was no unusual prominence of the superficial abdominal veins. The abdomen measured 105 ctm. in circumference at the level of the lowest ribs.

EXPLORATORY LAPAROTOMY

was performed on August 6th. The parietal peritoneum being divided, the omental tumor was seen presenting, and fluid and colloid material issued from the wound. The patient died two days later.

Autopsy, seven hours after death. The abdomen was enormously distended, tense, and hard on palpation. The entire peritoneum, both visceral and parietal, was infiltrated with nodular tumors of a pale, translucent material. The coils of small intestine were bound together, partly by adhesions of inflammatory origin, and partly by the union of contiguous masses of tumor in the peritoneum. The omentum was infiltrated and greatly thickened, covering the small intestines like the back of a turtle. The omental tumor measured 25 ctm. from above downward, 45 ctm. from side to side, and was 7 ctm. thick. It weighed 4.1 kilograms. The spleen was enlarged, but appeared to be normal in structure. It was surrounded by a mass continuous with the omentum, measuring 6 ctm. in thickness. The wall of the stomach was infiltrated with tumor masses. Its mucous surface was pale aud slightly pigmented in places, but there were no ulcers or abrasions. The orifices of the stomach were normal. The small intestine and mesentery were so matted together that the former could not be opened. The mesentery, in places, was as much as 10 ctm. thick.

Microscopically, the tumor was found to consist of a fibrous stroma, containing large alveoli lined with epithelial cells undergoing colloidal degeneration. It was only in the more recent growths, however, that this structure could be made out, as the sections in general showed simply fibrous material without any definite arrangement.

Dr. Ferguson then presented a heart showing lesions of

ACUTE PERICARDITIS.

The specimen was removed from the body of a man aged eighteen years, who had been admitted to the New York Hospital on January 31, 1888. About two years ago he had had an attack of "rheumatic fever," since which time he had been in apparent good health, except that he was short of breath on exertion, and had had occasionally palpitation of the heart. Six days before admission he had another attack of rheumatism following exposure. Examination showed an enlarged superficial cardiac area to the left, the apex being in the mammary line in the sixth intercostal space. A systolic murmur, not transmitted, was heard at the apex. Over the aortic area was heard a double murmur, the diastolic being the louder of the two. This murmur was transmitted upward into the vessels of the neck. A week later no murmur was audible over the aortic area, but there was a loud bruit in the vessels of the neck. A loud blowing murmur also was now heard at the apex and transmitted toward the axilla. The patient died on February 14th.

Autopsy, seven hours after death. The heart appeared to be very large, it being uncovered by the lungs throughout almost its entire extent. It weighed 430 grams. The pericardium contained 500 c.c. of turbid serum and pus. The pericardium throughout was covered by recent lymph. The ventricles were dilated and the ventricular walls hypertrophied. The cusps of the aortic valve were thickened and retracted. There was

ATROPHY OF THE TENDINOUS CORDS

of the mitral valve, and one of them had ruptured through ulceration, presenting two club-shaped extremities. There was fat in the muscular tissue of the walls of both ventricles and in the fleshy columns.

The spleen was large, hard, and dark in color. The liver presented the appearances so common in this organ in cardiac disease. The kidneys were large and congested, and the cortices swollen and opaque.

Dr. Van Santvoord said that he had a heart which he had been intending to present to the Society for some time, in which there were lesions of the chordæ tendineæ very similar to these. During life a loud and musical murmur had been heard. The patient had died in Randall's Island hospital, but unfortunately no previous history had been obtainable. He attributed the musical character of the murmur to the evenness of the lesions.

The President referred to the heart presented at the last meeting by Dr. Biggs, in which a systolic musical murmur, heard at the apex, was produced by a chorda tendinea running through the ventricle.

Dr. Ira Van Gieson presented some microscopical specimens illustrating

FAT-NECROSIS IN THE PANCREAS.

The specimens were taken from a woman aged eighty. In the superior border of the pancreas, about midway between the head and tail, was a soft, yellowish-white nodule, about five mm. in diameter, having a degenerated pasty centre. In the tail of the organ was a similar superficial nodule the size of a pin's head. A portion of the soft centre of the larger nodule examined microscopically in the fresh condition, consisted of larger and smaller, rather opaque globules, some of which stained with osmic acid. In sections through the nodules, amorphous masses were seen in places partially filling up the fat-spaces; in other places the degenerated fat-cells had coalesced, forming irregularly shaped necrotic masses, which stained brightly with eosin. The lesion seemed to be produced by the coalescence of necrotic fat-cells. Some of the acini of the pancreas contained hyaline cast-like bodies surrounded by the compressed cells of the acinus. Fat-necrosis has been studied by Ponfick (*Virchow's Archiv*, 56, p. 541), Chiari (*Prag. Wochenschrift*, 1883, 30-31), and Balser (*Virchow's Archiv*, 90, p. 520). The latter author found the lesion present in the pancreas in five instances in twenty-five autopsies, and recorded a case in which the lesion occurred in the omental fat, and extensively in the pancreas, which was the seat of fatal hemorrhage. Balser is disposed to think in this case that the fat-necrosis, by producing the pancreatic hemorrhage, was the indirect cause of death.

Dr. Ferguson said that he had made it a practice to examine the pancreas at his autopsies for some time past, and he had come to the conclusion that fatty necrosis of this organ was nearly always present. The fat might be found in the cells, evenly distributed throughout the pancreas. This occurred usually, though not always, associated with parenchymatous degeneration of other organs. Then again, the pancreatic cells might be unaffected, while large masses of what seemed to be fat was found in the interior of the lobules, the pancreatic tissue being destroyed. These masses were of a brownish color, and were frequently of sufficient size to be seen by the unaided eye. More striking, however, on gross inspection was the accumulation of fat along the planes of fibrous tissue, which might be so great as to cause destruction of the lobules by pressure.

When the masses within the lobules were treated with a weak caustic alkali, they sometimes disappeared. At times the brownish amorphous material on the outside disappeared on the application of weak acids, and bodies having the appearance of fat remained. These were, however, only in part soluble in ether, and what remained seemed to be leucin. He did not think that fat necrosis of the pancreas was the cause of hemorrhage in the organ, as he had never seen any evidence of this in his autopsies. He did not know why the fat was generally brownish in color, unless it was a result of the action of the secretion of the gland.

Dr. Van Gieson said that he was not inclined to believe that there was any causal relation between fat-necrosis and hemorrhage. These areas of fat-necrosis were observed as small, soft, circumscribed masses, but were not at all the same as lipomatous growths. Fat-necrosis was not always confined to the pancreas, and the speaker believed that it had also been observed in the form of little nodules in the peritoneum.

The President asked whether there were any gross appearances in the pancreas which would lead one to suspect the existence of fat-necrosis.

Dr. Van Gieson replied that, when extensive, it could be recognized by the presence of the brownish nodules, but in many cases these nodules were microscopical in size.

The Society then went into executive session.

Long Life without Exercise.—The Rev. William Davies, of Hereford, died in 1790, aged one hundred and five years. During the last thirty-five years of his life he never used any other exercise than that of just slipping his feet, one before the other. from room to room. He never lifted his feet or went down stairs. His breakfast was hearty, consisting of hot rolls, well buttered, with a plentiful supply of tea or coffee. His dinner was substantial and varied. At supper he ate hot roast meat, and always drank moderately of wine. He had never had gout, stone, paralysis, or rheumatism, but was blind for a number of years.

Kings' Expenses.—Edward the First paid 3 shillings sterling on the day of the queen's churching, " in oblations to mass." To the brethren at the Hospital at Rhuddlan, 1 shilling and 1 penny; for the carriage of figs and raisins to Aberconway, 1 penny. Charles the Second, for grinding cocoa-nuts, £5 8 shillings. To Mr. Pears, for dissecting a body before the king, £5 1 shilling. To Mr. Knight, for bleeding the king, £10 10 shillings. For a receipt for chocolate, £227. For weighing the king, £1. To a bone-setter, for attending the Duchess of Monmouth, £10. For 3,685 ribbons distributed with the royal touch, to cure King's evil, £107.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Adjourned Meeting, held March 21, 1888.

Robert Abbe, M.D., in the Chair.

Dr. Charles A. Powers presented a case of

FRACTURE AT THE INNER END OF EACH CLAVICLE,

which occurred in a man aged twenty, who presented himself at the Chambers Street Hospital March 3d, with a history of having slipped on a car track about half an hour previously, falling on the left shoulder. He was found to have a fracture of the left collar-bone just within the junction of the inner third with the outer two-thirds. The inner fragment was markedly drawn up and directed slightly forward, the outer fragment being displaced downward and the shoulder dropping in.

Some eight weeks previously the patient had sustained a fracture of the opposite clavicle one inch from the sterno-clavicular articulation, the inner end of the outer fragment being displaced backward to a very marked degree, causing considerable dyspnœa and dysphagia, as he had been told by the patient and the hospital surgeon who treated him at that time. At present there was union on the right side and the functions were excellent, but there was marked deformity, one being able to lay the thumb into a deep sulcus at the outer end of the inner fragment.

Dr. Powers called attention to the rarity of fracture at the inner third of the clavicle, and said that of four hundred and ninety-eight fractures of that bone treated at the Chambers Street Hospital during the past ten years, only fourteen, or less than three per cent., were located at the inner third. This was about the proportion given by Hamilton, who said that of one hundred and seven cases in only four was the fracture at the inner third. He also spoke of the singularity of dysphagia in the right fracture, while the œsophagus curved to the left at the root of the neck. The patient said the dysphagia lasted about a week.

It was said that this fracture occurred almost invariably from direct violence, but, according to the patient's story, it was the result in both instances, in the case presented, of indirect violence.

The Chairman thought there would have been no objection, in the first accident, to replacing and wiring the fragments together. He agreed with Dr. Powers, that the injury was located too far outward, in both instances, to suggest separation of the epiphysis instead of fracture of the bone.

Dr. G. L. Huntington then read a paper on

THE OPERATIVE TREATMENT OF OLD INJURIES OF THE ELBOW-JOINT,

which will be published in The Medical Record.

Dr. F. W. Murray said he had seen a considerable number of cases of fracture at the elbow, but none in which he had done partial resection, as suggested by the author, although he would not hesitate to adopt the procedure in a suitable case.

Dr. Powers had hoped to show two or three cases of fracture of the neck of the radius accompanied by posterior displacement of the ulna, treated by him at the Chambers Street Hospital, in which the functional results were only fair, with failure to obtain complete extension and complete flexion.

Dr. F. W. Murray read a paper entitled

A RARE FORM OF ANEURISM OF THE INTERNAL PUDIC ARTERY,

which will be published in The Medical Record.

The Chairman said he had had the pleasure of assisting Dr. Murray with the operation. There was some doubt as to the origin of the profuse hemorrhage which took place, his feeling being that it arose from the sciatic artery, while Dr. Murray thought it was from the internal pudic. Dr. Murray's diagnosis was verified at the autopsy. The management of the case proved most satisfactory. He saw no other way of treating such a case with equal freedom from danger.

NEPHRO-LITHOTOMY.

Dr. Andrew J. McCosh read a paper with this title, in which he also gave the history of a successful case. Ten years ago it would have been considered foolhardy to have cut into a comparatively healthy kidney in order to remove a stone. The surgeon would have waited until the affected kidney had become destroyed by a suppurative process; or, if he had been forced to interfere, he would have removed the entire organ. Apart from the conservative advantage which nephro-lithotomy possessed, it had the additional claim of being much less dangerous than either nephrectomy or nephrotomy for calculous pyelitis.

His case was that of an unmarried female, aged twenty-eight, who had complained since childhood of pain in the right loin. During the past few years it had become much more severe, and during the past eighteen months she had been unable to do any work, on account of exacerbations caused by any exertion or sudden movement. The pain was of a gnawing and throbbing nature, felt principally in the right lumbar region, extending across the abdomen to the linea alba. There was marked tenderness on pressure toward the kidney. There had been no vesical disturbance. The attitude was peculiar; the right loin was bent inward, and the upper part of the body was projected forward and toward the right. Various diagnoses had been made by different physicians.

Dr. McCosh first saw the patient eighteen months ago, and felt confident there was stone in the kidney, although nothing was found in the urine to confirm the diagnosis until some time afterward, when pus and some blood-corpuscles were discovered. Nephro-lithotomy was performed January 9, 1888. A vertical incision was made along the outer edge of the erector spinæ muscle from the last rib to the crest of the ilium. Instead of the kidney being in the upper part of the wound, its superior extremity was found two and a half inches below the last rib, and his index-finger thrust down over the crest of the ilium barely reached its lower end. A loop of small intestine was seen, but the colon was not visible during the operation. A hard body, evidently a stone, was felt in the pelvis of the kidney. Finding it difficult to lift the kidney and bring its pelvis into view, he made a transverse incision, three inches long, running outward along the iliac crest. The kidney was held up and its pelvis exposed in the wound, and a rough mulberry calculus, weighing 120 grains, was extracted. The kidney was apparently healthy. A drainage-tube was fastened into the opening in the renal pelvis by a thin catgut suture passed through the perirenal fat. The upper half of the vertical and the anterior half of the transverse incision were closed, the rest of the wound was left open, and a drain was passed down alongside the kidney. His principal reason for not closing the wound was that the opening in the kidney was situated inside the pelvis, and he feared infiltration of urine within the iliac crest. The drainage-tube in the pelvis of the kidney was removed on the third day, and the other tube was removed two days later. No infiltration of urine took place, and the patient rapidly recovered. No urine escaped by the wound in the loin after the twelfth day. She was discharged cured at the end of the fourth week.

The chief difficulty in making a diagnosis in this case was the absence for so long a time of any renal signs. Regarding the misplacement of the right kidney in this case, he stated that Morris had collected 8,842 cases in which the location of the kidneys had been noted at autopsy, and in ten of these one or the other kidney was misplaced. Leaving out the horse-shoe kidney, the most common displacement was that in which the kidney was situated over the sacro-iliac synchondrosis, as in his own case. When found in this position the arteries arose, as a rule, from either the bifurcation of the aorta or common iliac. The left kidney was much more commonly displaced than the right.

Gross, in December, 1886, published a collection of thirty-four cases of nephro-lithotomy with three deaths. Since then Dr. McCosh had collected reports of eighteen cases with three deaths. Compare with this death-rate of 11.52 per cent. out of fifty-two cases, the death-rate of nephrotomy for calculous pyelitis, reckoned by Gross as being thirty-three per cent., and that of lumbar nephrectomy, given by the same writer as 36.93 per cent.

Gross had collected twenty-nine cases in which an exploratory incision had been made for suspected renal calculus, none, however, being found, and all the patients recovered. Dr. McCosh had collected five additional cases, with two deaths, but in the two fatal cases the autopsy revealed renal calculus, although none had been found at the operation.

Dr. Magnin said, with regard to the method of operating, that he had seen Terrier make his transperitoneal operation, consisting in cutting down along the outer border of the rectus muscle, going through the anterior and posterior layers of the peritoneum, and uniting the peritoneal surfaces. This operation did away with the necessity for a small incision, and with the possibility of infiltration of urine in the pelvis. He did not employ drainage.

OUR PARIS LETTER.

(From our Own Correspondent.)

SIMULTANEOUS CONTRAST OF COLORS—ANTI-RABIC INOCULATIONS—SKIN-GRAFTING—ACTION OF ACIDS ON THE FUNCTION OF THE STOMACH.

Paris, April 6, 1888.

A tribunal court in Germany lately made a curious application of the laws of M. Chevreul, the venerable French centenarian and chemist, on the simultaneous contrast of colors. A blacksmith, striking on an anvil, let go his hammer, which struck his assistant near the left eye. The wounded man, after having received the necessary care, was pronounced absolutely cured by the medical man after a few days. The victim of this accident, however, persisted in complaining of severe pains in the eye struck by the hammer, and pretended to have lost the sight in that eye. Ophthalmologists were consulted, and they all unanimously declared that the allegation of the man was without foundation. In consequence of this decision, the master interested in the affair refused all indemnity, and a lawsuit was the result. All the old, known ruses employed to detect false myopes, false presbytes, and one eyed persons were adopted in this case, when one of the experts, recalling the principle of one of the laws of Chevreul, tried the following experiment: On a black hand-screen he traced a few words in green. On the nose of the pretended one-eyed man he placed a pair of spectacles, with a red glass for the right eye, a white glass for the left. Then handing the screen to the man, he asked him to read what he had written. Without the least distrust, the man read out the words. The expert then asked him, "Is it really with the right eye that you have read?" "Certainly," replied the man, "as I cannot see with the left eye." "Well!" exclaimed the expert, "this is not possible; you could not read with the right eye green characters on a black surface, because the red glass color, complementary of green, effaces them for this eye, and confounds them with the black of the screen. It is with the left eye alone and through the white glass that you have been able to read them. Therefore you are not blind of one eye." The tribunal considered the experiment as decisive, and rejected the suit of the complainant. The French papers have been full of this affair, as they consider it a conquest for them.

A soldier by the name of Alphonse Marinot, of Paris, aged twenty-three, was bitten on the right forearm on February 15th last at ten o'clock in the morning, by a mad dog which he was trying to kill. He immediately went to the hospital of Val-de-Grace, where the wound was cauterized, and at eleven o'clock he was taken to Pasteur's Institute, where he underwent the first inoculation. From February 15th to March 5th Marinot followed the Pasteur treatment with the greatest regularity, and on the day of his discharge from the hospital, one of the professors of Val-de-Grace, considering that the man was perfectly safe, actually delivered a lecture on the advantages of the anti-rabic inoculations. On Thursday evening, March 29th, Marinot was seized with pains in the right arm, and on the evening following he felt himself obliged to return to the hospital of Val-de-Grace, where symptoms of rabies declared themselves, and he died on Sunday, April 1st, at six in the morning. The man, who was aware of the gravity of his case, buoyed himself with the hope that, as scarcely an hour had elapsed between the time that he was bitten and the first application of the anti-rabic treatment, he would escape the effects of the dire disease.

Grafting has been practised not only with the human skin but with that of animals, and with some degree of success. The skin of frogs has also been tried. Dr. Rodard, in a communication to the Société de Biologie, spoke in praise of the grafting he had practised with the skin of the common domestic fowl, which was attended, in many cases, with results much more rapid than with the skin of the frog, particularly in a case of severe burning of nearly the whole of the scalp of eight months' standing, in a young child of two years. The reparative process of the parts burnt was *nil* during this period; suppuration during all that time was very abundant, which so much enfeebled the patient as to threaten his life. The grafting with the skin of the frog not having given rapid results, Dr. Rodard practised grafting with the skin of the fowl, and in two months he obtained a regeneration of the skin of seven centimetres in the antero-posterior direction of the skull, by eight centimetres in the transversal direction. The author remarks that the skin of the fowl is supple, fine, and vascular. It stretches out and adheres well on the surfaces without being resorbed, thus producing important epidermic islets, which, in developing and extending, form new tissues, supple and different from the ordinary tissues of cicatrices. The skin should be taken from under the wing of young fowls; it should not be deprived of cellular tissue and should not contain fat. The transparent fragments should measure from a half to one centimetre. Sutures are unnecessary, as the skin becomes easily adherent and does not get displaced. The wound should be aseptic and the dressing performed with scrupulous care; that with iodoformed gauze, with a layer of cotton wadding slightly compressed, appeared to the author to be the most suitable.

In an article published in the "Bulletin de Thérapeutique," on the action of acids on the functions of the stomach, Dr. Jawroski, after having experimented with acids in seventy subjects, found that the stomach bore acids much better than is generally believed. A little time after the administration of a solution of hydrochloric acid, one finds on microscopic examination fragments of cellular nuclei, which had not been remarked before. In cases of hypersecretion (of acid gastritis) it is found that acidulated drinks diminish the secretion of hydrochloric acid. The author concludes: 1. The secretion of pepsin depends on the secretion of hydrochloric acid. 2. The administration of acids with a therapeutic object furnishes in the first place the acid, and then provokes the secretion of pepsin. 3. The employment of acids is the best means for augmenting the secretion of pepsin. 4. Acids provoke an emigration of the leucocytes of the vessels of the mucous membrane of the stomach. This is why one finds, in the cases of hypersecretion of hydrochloric acid in an empty stomach, débris of cellular nuclei. 5. The acids contained in the stomach arrive in the duodenum, where they provoke anti-peristaltic contractions, and the food, mixed with bile, returns into the stomach. 6. These phenomena explain the biliary coloring of the contents of the stomach in the case of acid dyspepsia (hypersecretio acida continua), and how in this affection digestion is so slow. Water strongly charged with carbonic acid, introduced into an empty stomach, provokes a more abundant secretion of gastric juice than would a corresponding quantity of distilled water. A certain quantity of water charged with carbonic acid disappears much more quickly from the stomach than a corresponding quantity of distilled water.

At a recent meeting of the Société Médicale des Hôpitaux, Dr. Blachez exhibited some pathological specimens taken from an old woman, who was admitted into his ward with all the symptoms of advanced cachexia. At the autopsy, a voluminous cancer was found in the stomach, but which did not affect the orifices. The author remarked that this woman had never presented any phenomena of dyspepsia or of vomiting.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PATHOLOGICAL SOCIETY—SOME UNUSUAL EXAMPLES OF MALIGNANT DISEASE OF THE LARYNX—RARE FORMS OF RENAL CYSTS—THE NATIONAL PENSION FUND FOR NURSES—NURSES AND THEIR EARNINGS—THE LATE DR. NICHOLAS PARKER.

London, April 10, 1888.

Some interesting specimens and cases were brought forward at the last meeting of the Pathological Society. Mr. W. S. Colman related three cases of diphtheria, on which subject a brief discussion took place. Dr. Norman Moore showed some specimens illustrating some anatomical relations of chronic joint-disease. Dr. W. B. Hadden brought forward a case of cyst of the heart, and Dr. G. N. Pitt referred to a specimen he was showing of a cardiac cyst. Dr. Semon and Mr. Shattock read notes of some cases of malignant disease of the larynx which presented some unusual features. One was a case which was only diagnosed during life by the general symptoms and a process of exclusion, as the patient would not permit any laryngoscopic examination. Nor would he submit to tracheotomy, which was advised. The patient was eighty-one years of age, and death shortly occurred. An intra-laryngeal growth was found occupying the greater part of the larynx below the cords. On microscopic examination it proved to be an alveolar sarcoma. No case of laryngeal sarcoma had been previously recorded in which the patient was so advanced in life. The second case was one of epithelioma, occupying the right half of the larynx, for which partial excision of the organ was practised, but death ensued on the third day from pneumonia. At the operation a small isolated growth was found on the lower half of the left vocal cord. Such a growth might be interpreted as evidence of direct cancerous inoculation. Professor Bergmann had lately shown to the Berlin Medical Society a case of carcinoma affecting two exactly opposite similar spots of the upper and lower lips. The third case was one in which carcinoma within the trachea was continuous with carcinoma of the thyroid. Death ensued from hæmoptysis. Post-mortem examination of the growth showed it to be a cylinder-celled carcinoma. The right recurrent laryngeal nerve was involved in the growth. Double pneumonia of the lower lobes was found.

Dr. H. W. G. Mackenzie showed a kidney containing cysts in which were calculi. The specimen was obtained from a woman, aged sixty-nine, who had died from cerebral hemorrhage. Cysts were present in both kidneys, but only those in the right kidney contained calculi. There was no calculus in the ureter, pelvis, or bladder, and no communication between the pelvis and the cysts. Dr. Mackenzie remarked that no such case had previously been brought before the society, but a somewhat similar specimen was referred to by Dr. Dickinson in his work on "Kidney Diseases." The presence of cysts without calculi in one kidney showed that the cysts were not due to the calculi. It was not probable that they were due to obstruction by small concretions. Assuming them to be due to obstruction of tubules, the obstruction must have been incomplete, or else the cysts must have communicated with non-obstructed tubules so as to permit some flow of urine through the cysts.

The National Pension Fund for Nurses bids fair to become a great success. Four city merchants have each contributed the munificent sum of £5,000, and the total amount thus raised ($100,000) has been deposited in Chancery as security for the annuitants and policy-holders. It will be invested in such securities as are authorized by the Court of Chancery, and the dividends will be paid to the bonus fund until the accumulated premiums amount to £40,000. The nucleus of a bonus fund has already been formed. Subscriptions and donations to the amount of £6,000 are already announced, among the donations being one of £5,000 from Mr. Junius Morgan, one of the four gentlemen who had already given a like amount to found the pension fund. Subscriptions will be sought from persons interested in nurses or concerned in their training. The number of subscribing members will doubtless be very large. Nurses in general are not, as a class, given to saving up anything against a rainy day, but many will doubtless enroll their names as contributing members to the fund when they learn the advantages offered. A nurse, aged twenty-five, who pays to the fund £2 10*s.* a year ($12) will insure a minimum pension of £15 a year, after sixty years of age, for the rest of her life. A further payment of 15*s.* a year will insure an allowance of 10*s.* a week during the time she may be permanently disabled by sickness or accident.

One great cause of the general improvidence of nurses is the uncertainty and irregularity of employment among those who work for themselves. Hence the eagerness of many to join some nursing institution. Many such are carried on by the proprietors as a business, and a very paying one too. For instance, I have been told of nurses for whom 42*s.* a week was paid by their patients, but who only received 25*s.* out of this, the remainder being retained by the institution. In some of the so-called "nursing sisterhoods" the pay actually received by the nurses is still less.

A death of some note is that of Dr. Nicholas Parker. He practised for some years as a physician in London, and was for some time on the staff of the London Hospital. As a teacher he was a great favorite. When at the zenith of his fame, however, he suddenly announced his intention of retiring, to the great disappointment of those who expected great things from him. Being possessed of an ample fortune he carried out his intention, and resided for some years chiefly in Paris. During the last quarter of a century, therefore, he but seldom entered medical circles, but devoted himself to social and musical pursuits.

THE QUESTION OF RESPONSIBILITY—AN INTERESTING LEGAL CASE.

To the Editor of The Medical Record.

Sir: On May 15th, while driving along the highway, a surgeon (R.) was hailed and asked to go into a house to see a woman who had injured her leg by falling from a table. On hearing that there was another medical man (S.) already with her, R. hesitated to accept the invitation, when the husband (F.) came out and requested R. to go in and help the doctor, who, by the way, had been summoned from his office by special messenger some little time before. R. then went into the house, and found S. examining the woman's leg. She lay on the floor, complaining of great pain. R. asked S. what he found to be the matter; S. replied that he did not know. She was a very stout lady, weighing about two hundred pounds. R. suggested that in order to make a careful examination, it would be best to put her under the influence of ether. S. agreed to this; wrote out an order for some, and, on its arrival, administered it. R. stood by until she was under the influence of the anæsthetic. They then examined the leg together, with care. All that they found was a ruptured ligamentum patellæ; no crepitus, no shortening, no displacement of the foot or leg; one leg was exactly the same as the other in length and position, except that the patella was drawn up by the extensor muscle of the thigh. S. told R. he had no splints, and R. lent him one of his. It was a long, straight splint, which extended from the head of the thigh-bone down to the foot, with a foot-piece attached. S. padded the splint well, and R. assisted him in applying it. It was first placed in position by several straps, about two inches wide, of rubber adhesive plaster encircling the limb and splint, and then a bandage was applied. The splint and the leg (almost up to the head of the tibia) were first enclosed in a bandage, and then another bandage was applied above the knee up to the head of the thigh, also enclosing both leg and splint. Then the cap of the knee was brought down and kept in position by straps of rubber adhesive plaster long enough to go around the limb and the splint, and half again. A bed was prepared in an adjoining room, and R. assisted S. and several others in lifting the patient into the bed. R. then told the people of the house that, as far as he (R.) was concerned in the case, he had nothing further to do, and that they might as well settle with him at once for his trouble in assisting S. That S. was the first (by thirty minutes) to be in attendance, and the case was his; for S. had been especially summoned to it, while he (R.) was merely a casual assistant. R. asked $10 as his fee. F. said that he had no money just then, but would pay the fee, which he subsequently did. R. left the house; S. remained there after R.'s departure; F. came out to the sidewalk with R., and asked him if he deemed S. a competent man. R. replied, "He is a legally qualified physician, and I should think he was all right." R. then got into his buggy and drove off. R. never saw the case again, nor was any request ever again made to him to see it, either by the family or by S. R. left S. in the house with his patient, whom S. visited again that night, and day after day for three months. He alone removed the splint that had been put on, and returned it to R.'s house nine days after the accident, *i.e.*, May 24th, with his compliments, adding that he was much obliged. It appears from the sworn evidence of S., subsequently, that when he removed this wooden splint he found the leg in perfect position, and was careful to keep it so while he applied a plaster-of-Paris splint on the leg. This last he left on for six weeks, *i.e.* till July 5th. But when he removed the plaster-of-Paris splint he says that he found there had been a fracture of the femur, and that the bones overlapped two inches and a half. Meanwhile R.'s fee of $10 was paid; $5 on June 5th, and the other moiety on October 1st. But on neither occasion was any reference made to any deformity; in fact, R. hears not a word about such a thing, either directly or indirectly, till fifteen months *after* the last payment, when, without any previous warning, legal notice is served on him, in January, of an action for malpractice, entered by F. against R. *alone;* who then and there receives his first intimation of the fact, alleged by S. to have been known to him (S.) in the July after the accident. But it should be mentioned, as it appeared in evidence later on, that, in the meantime, *i.e.* in December, seventeen months posterior to the accident, a third doctor (W.) had been called in by F., and this suit against R. then determined upon. A little more than a year elapsed, when, February last, the case came to trial. The judge gave a general instruction to the jury, who, to everyone's surprise, awarded the plaintiff $2,000 damages. Notice of appeal was promptly given by R.'s counsel. It was duly argued March 3d. The judge takes a week to deliberate, and then states—March 10th—that he had looked carefully into the case, and as no evidence had been adduced to show that R. was completely responsible, this alone would justify him in granting the appeal for a new trial.

COMMENT.—The case so fully reported above is one that will not only be anxiously watched in its future stages, if any, through the courts, but is, even now, full of suggestiveness to the profession. And whether further proceedings should give evidence of *bona fides* on the part of the plaintiff (F.), or should develop proofs of conspiracy, either for the purpose of shielding S. or of levying blackmail upon the practitioner deemed best able to pay, the medical community owe much to their confrère for his determination to fight the case to a finish, and thus to establish a precedent that may be instrumental in making such actions well-nigh impossible in the future.

At the very outset the question naturally arises, "When does legal responsibility in a case of emergency cease?" It would be well if medical men could agree on this point: and it is satisfactory to know that the Medico-legal Society of Chicago is already discussing the subject, on which a paper has been prepared by one of its prominent members. In this particular case there seems not to be room for questioning the conclusion that the responsibility of R. ceased with the termination of his first, last, and only visit. Indeed this would appear to be fully conceded by F., when he agreed, at the time, to pay R.'s fee, as assistant; which agreement he carried out without cavil, or hint of suspicion that it might be necessary for him thereafter to go behind this concession. And yet every circumstance upon which an action for damages could be based was known three months before the final payment of R.'s fee was made; nor, apparently, was any action thought of till another interval of over a year had passed by. Part II., Art. v., Sect. 4, of the "Code of Ethics of the American Medical Association" says: "In case of accident or sudden emergency, one or more physicians are often sent for by alarmed friends. Courtesy should assign the patient to the first of these that arrives, and he should select from those present such additional assistance as he may deem necessary." This is just what happened in the case. And S., not simply by accepting the services of R., as his assistant, but by his every subsequent act, showed clearly his sense of his own responsibility as *the* attending physician, and thereby absolved R. —who, by the way, had never visited any member of the household before—from all professional or legal responsibility in the matter, as far as it was in his power to do so. For instance, he removed the wooden splint in nine days. R. is not consulted as to this step; fortunately S. is able to swear that he found everything going on well at this stage. And even supposing, for the sake of argument, that there could have been *joint* responsibility up to this point, surely the fact that S. saw fit to change the treatment, which had been jointly agreed upon, without consulting R., in his absence, and without even acquainting him of the change, must relieve R. of his share, if any, of accountability.

We cannot do better than cite the learned judge's reasoning when he granted a new trial. When two persons are called to do a duty jointly, it is essential to have it well settled, in a case for damages, whether *one* was completely responsible, or *both*. If both made a mistake in their diagnosis, or failed to exercise due care, then their responsibility would be equal. But all the evidence points the other way. If the bone was broken when both had their opportunity, but did not make the discovery, it is hardly fair to throw the whole charge upon one, and that one he who had, by joint consent, stepped out, leaving the other his full swing. It does not appear that the defendant (R.) had, at the time when a re-examination of the injured limb was possible, a chance. The main idea of S. is to exculpate himself and throw responsibility upon R., which is curious, in view of the fact that S. alone removed the wooden splint, and substituted one of plaster-of-Paris. The judge proceeded to state that a new trial and fresh evidence were necessary to prove that, if R. had any responsibility at all, it must be jointly with S. At this point the plaintiff's attorney naively suggested that his honor might reduce the damages one-half; a tacit admission, it would seem, that he did not expect a second time to be fortunate enough to secure a snatch verdict. The judge promptly rejected the overture by saying: "The question has to come down to one of joint responsibility." A casual review of this case discloses the great risk to which even the most experienced men in the profession are constantly being exposed; indeed the more eminent their position, and therefore, as a rule, the more lucrative their practice, the greater their liability to loss at the hands of an ignorant jury. The valuable gratuitous services rendered by medical men to the needy and suffering poor are too well known, and in most cases appreciated, to be more than mentioned; and yet it is in this very stratum of society that danger lurks. Here is a graduate of a medical college whose standard is a high one, a practitioner of twenty-three years' standing, whose surgical skill has been tested in the naval and military service of his country, as well as by long and successful civic practice, called upon by men who cannot know anything of the ethics of professional life, and who could not understand them if they did, to sell his honor for $2,000, or defend it at the maximum of expense to himself, but the minimum to those who may be expecting to make a good thing out of it. We would venture to throw out these suggestions to medical societies as worthy of consideration, in view of the opportunity for blackmail which is opened by the admittedly low standard of examination for admission to a few of our colleges: 1. That they should discuss, and thoroughly, the degree of responsibility incurred by the expert called in at cases of emergency. 2. That they should endeavor to secure legal provision for the furnishing of security for costs in all suits demanding damages for alleged malpractice.

This last, in particular, would estop many an action brought by the impecunious against the well-to-do practitioner, in hopes of making the latter pay for injuries made permanent, either by the patient's own gross carelessness, arrant folly, wilful inattention, or perverse disregard of the attending physician's plainest instructions.

SUBSCRIBER.

SOME OF THE REASONS WHY QUARANTINE IS NOT A SUCCESS.

To THE EDITOR OF THE MEDICAL RECORD.

SIR: To all persons, and especially physicians, living at sea-ports that enjoy considerable commercial prosperity, and are accordingly exposed to all the contagious and infectious diseases that may exist in the ports with which they have communications, the agitation of the question of National Quarantine, which is but a forerunner of a larger question, International Quarantine, is very interesting and of vital importance. It is of importance alike to the physician, merchant, and statesman, and must be viewed from all sides. In this place I can only express my views, and call attention to certain facts as a physician.

All preach, whether they practise, that a thing that is worth doing at all is worth doing well; if there is any benefit in quarantine, it is worth doing it well and thoroughly, and the only way for it to be done thoroughly is by placing it under national control, where uniformity can be obtained and the expense borne by all. The quarantine system at New Orleans is of incalculable benefit to the city and State, but it also benefits all the Southern States in regard to yellow fever, and the entire country in regard to cholera; and it is but just that all assist in the expense. These facts have all been stated before, and need no comments.

I would like to call attention to one condition, which must be remedied before the full benefit of quarantine as a preventive measure can be of any great avail, *i.e.*, the unreliability and insufficiency of consular health reports.

The two principal purposes of a quarantine system should be to prevent the introduction of contagious or infectious diseases from a foreign port, and to make it possible for trade between two ports to be as uninterrupted as possible, consistent with the safety of each. This last is often overlooked by physicians when they meet to consider this question, and accounts for the fact that consular health reports have had but very little attention paid to them.

Undeniably, a port that is free from all infectious and contagious diseases should not be subjected to the same rigid quarantine restrictions that it is right to impose on an infected port. Every detention is prejudicial to both the port of departure and of entrance.

The only way, at present, in which it can be determined whether a port is infected or not, is by means of consular health reports. Most physicians who have had any experience in quarantine work will admit, I think, that they pay but little attention to such reports, as they are utterly unreliable; they are issued by men who know nothing of disease, and do not know when such diseases are in the port, and are liable to be affected by idle rumors. As an instance of their unreliability, I will state that I had in my possession three bills of health from the same port, issued within two days; one, from the United States consul, certifies that there is one case of small-pox in the hospital; one, from the English consul, is "clean," stating that there is no such disease in the port; and one from the secretary of the Board of Health, dated the same as the one issued by the English consul, states that there are seven cases in the hospital, three having been admitted that day. In another case the bill of health was "clean," but private instructions from a physician stated that small-pox was in the port; he had informed the consul to that effect, but he refused to accept his statement. In still another case the consul issued a "foul" bill of health, when the physician wrote me that he had examined the cases and that they were not small-pox.

The result of this uncertainty is, that at certain times of the year quarantine officers have to put under quarantine vessels from certain ports, when, in nine cases out of ten, if reliable information could be obtained, intercourse could be uninterrupted; and among the majority, quarantine laws and regulations are looked upon, and to a certain extent are, a nuisance instead of a benefit; due not to the system *per se*, but to the methods employed. This is but one of the faults that must be corrected before quarantine can be a success in all particulars.

Yours respectfully,
W. F. THORNTON, M.D.
BLUEFIELDS, M. R., NICARAGUA, C. A.

THE TREATMENT OF CANCER BY THE "SUCTION OF TOADS."—In a letter to *The Lancet*, Dr. W. Curran refers to a passage in Junius in which that writer says that "nothing keeps her [the then Princess of Wales] alive but the horrible suction of toads. Such an instance of divine vengeance would [he thinks] convert an Atheist." Professor Newton, of Cambridge, gives the following explanation of the passage: "During a certain period of last century live toads were applied as a supposed cure or as a relief to cancerous breasts. In the third volume of Pennant's 'Zoology,' page 389, edition of 1776, a letter is published, bearing date, 'Exon, August 29, 1768,' in which the process is described to Dr. Lyttleton, the then Bishop of Carlisle, by Mr. Patfield, a medical eye-witness. The toad was put into a linen bag, all but its head, and that was held to the sore, which the animal sucked greedily. A woman supposed to have been cured in this way was said to have had toads on her day and night for five weeks without intermission. Numerous other details are [he adds] mentioned in the letter, which is worth reading."

EARLY RISING is one of the characteristics of persons who live long lives. It is more important than total abstinence.

New Instruments.

AN EFFECTIVE NASAL SYRINGE.

By J. M. W. KITCHEN, M.D.,
NEW YORK.

IT is taken for granted that most practitioners have felt with the writer the need of an instrument suitable for cleansing the nasal and post-nasal cavities, that should be thoroughly effective, but not liable to get out of order, or be injurious in use, and yet be of moderate cost. The only effective instruments hitherto sold for this purpose, have been the costly complex atomizers, which are not easily managed or kept in order by the average patient. In use, they also have the disadvantage, in many cases, of over-stimulating the mucous membrane.

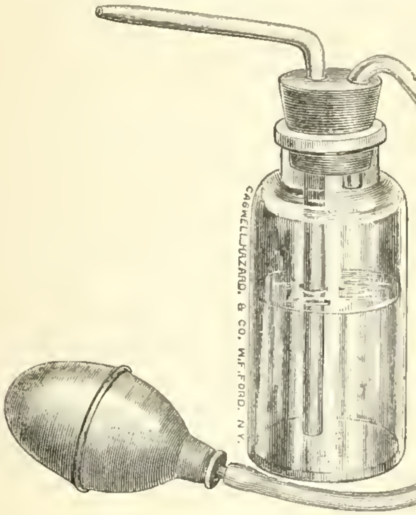

FIG 1.

Except in atrophic conditions, the process of cleansing should be attended with as little stimulation as possible. In most cases the object to be attained is simply to bring the fluids used in contact with the retained secretions, for the purpose of dissolving and diluting them. Then, if sufficient fluid is used, the secretions can be removed by the natural method of nose-blowing or gentle "hawking."

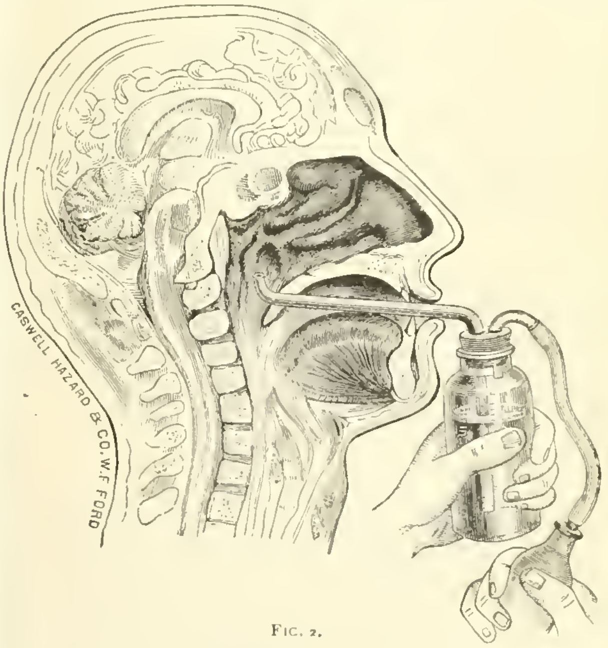

FIG. 2.

The nasal syringe shown in Fig. 1 will be found a most useful instrument for this purpose. It was suggested to the writer by, and is merely a modification of, the ordinary laboratory wash-bottle; but it is so exceedingly satisfactory in use that it is a wonder that it has not been long since adopted for this purpose.

It is inexpensive, cleanly, does not get out of order, is remarkably effective, and cannot do harm in use. As made by Mr. Ford, of Messrs. Caswell, Hazard & Co., it consists of a bottle of convenient shape for grasping, two rubber corks with glass antero- and post-nasal nozzles, and a single valveless rubber bulb and tube. The nozzles are of sufficiently heavy glass to avoid breakage, and are slightly drawn out at the orifices. The bottle can be partly filled by holding it horizontally with the nozzle in the cleansing fluid; repeated pressure on the bulb produces a partial vacuum in the bottle, and the fluid rushes in to take the place of the expelled air. When held perpendicularly, pressure on the bulb expels the fluid from the nozzle with a degree of force proportionate to the pressure exerted by the hand—in no case an excessive pressure.

A word as to the method of making post-nasal applications with this syringe. The syringe nozzle should be carried directly to, and held gently against, the posterior wall of the pharynx (see Fig. 2), and the lips closed tightly around the nozzle tube. Then, while the breath is drawn gently through the nose, at which time the soft palate is of course relaxed, the fluid can be readily propelled into the post-nasal space. This gentle method the writer has used for some years, and recommends it as being infinitely preferable to the forcible methods usually adopted.

In using this syringe, the patient should hold the head over a receptacle to catch any outflowing fluid, more of which is used in this syringe than in atomizers. If cleansing fluids were expensive, this generous use might be objectionable, but powdered borax and soda are cheap, and it is hardly to be supposed that 4 oz. complicated prescriptions will be recommended to patients with chronic catarrhal troubles.

Moderately alkaline water is all that is needed for this purpose. Deodorizers are not usually desirable. If any stench is present, it is a sign that the offending matter needs *removal*, not covering. Hence sufficient fluid should be used to effect this requirement.

168 West Fifty-eighth Street.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 21, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	5
Scarlet fever	189	30
Cerebro-spinal meningitis	4	6
Measles	66	7
Diphtheria	120	44
Small-pox	10	7
Yellow fever	0	0
Cholera	0	0

Are the Tertiary Products of Syphilis Infectious or not?—According to Zeissl, the question of the infectiousness and transmissibility of the products of tertiary syphilis can be summed up in the following conclusions: 1. The offspring of those having tertiary syphilis are, as a rule, healthy. 2. The secretion from broken-down primary sores and the products of the papular stage of syphilis brings forth a syphilitic reinfection in those affected with gummy nodes. 3. Inoculations with the secretion of gummy nodes have never succeeded. In opposition to these three arguments of those who do not believe in the infectiousness of tertiary syphilis, the following points can be raised: 1. By many authors it has been shown that tertiary syphilis is transmissible, even if in extremely rare cases. This probably depends upon the length of time since the existence of the primary lesion of the parent. On the other hand, it is not imperative that syphilitic parents should beget syphilitic children, as it is well known that even parents in the secondary stage have had healthy children. 2. Up to the present time there are but few cases of syphilitic reinfection in those with tertiary syphilis, and even these few are doubtful, since, in these cases, the course of the second infection was quite unusual. 3. Inoculation with the secretion of the products of tertiary syphilis are as yet only few in number, and negative results are never convincing. It is often seen that inoculation with the secretions of the primary and secondary lesions frequently fail. Besides the above, the following points favor the infectious nature of tertiary manifestations. Gummy nodes have a similar histological structure to that of the papule and primary lesion. In the same class of tumors belong, according to their microscopical appearance, the products of tuberculosis, lupus, lepra, and glanders. These are all granulomata, and the diseases are, as a whole, infectious, as is also shown by the demonstration of specific micro-organisms in them.—*Journal of Cutaneous and Venereal Diseases.*

A Good Showing for Hysterectomy for Fibroids.—Professor Carl Braun has published an account of thirty-eight cases of hysterectomy for fibroid, performed in the Vienna General Hospital, with only six deaths; that is to say, a mortality percentage of 15.5. The results which he had thus obtained were two per cent. behind those of Hegar, Kaltenbach, Bantock, and Keith, and about sixteen per cent. better than the results obtained by the Berlin gynecologists. Professor Braun is strongly in favor of the extra-peritoneal treatment of the stump, as both the cases in which it was treated intra-peritoneally ended fatally. According to him, the following are the indications for hysteromyomotomy: 1. Attacks of pain during menstruation, or in the intervals between the periods, which recur frequently, and render the patient unfit for work of any kind. 2. Functional disturbances from pressure on the neighboring organs, involving risk to life. 3. Severe metrorrhagia, in which a cure cannot be obtained by any less radical procedure. Instead of the aseptic sponges, he in most of his cases uses mull gauze which has been, for twenty-four hours before the operation, boiled in a one per cent. solution of sublimate, and which is afterward washed in clear water. Immediately before and during the operation the gauze is wrung out of a hot solution of thymol (1 in 1,000), and used for stopping the bleeding from the peritoneal surfaces after ligature of the blood-vessels. A solution of sublimate or carbolic acid is never brought into contact with the peritoneum. After the tumor has been brought forward the abdominal wound is temporarily closed by means of hooked forceps. The peritoneum of the abdominal wound is sutured above and below the stump, and the latter is fixed to the peritoneum of the abdominal wound by means of a mattress suture. Both the Fallopian tubes and the ovaries are separately ligatured with silk threads. Only after the closure of the abdominal wound by means of silk button sutures the tumor is removed, the stump being touched with the actual cautery and covered with benzoate of sodium. The extra-peritoneal treatment of the stump in cases of hysteromyomotomy is specially advantageous when the myomata are situated in the wall of the body and the fundus of the uterus, but less so in those myomata which are situated between the walls of the cervix, the lips of the os, and the broad ligaments.—*Wiener Medizinische Wochenschrift.*

The Mouth.—A mouth great and wide betokeneth wrath, boldness, and gluttony. A wide mouth, without measure, as though it were cut or stretched out, signifies a hard and cruel heart. A mouth that hath but little closing and a little opening signifieth a fearful, quiet, yet unfaithful man. A mouth that is very apparent and round, with thick lips, pointeth to uncleanness, folly, and cruelty. A big mouth, with little shutting and smiling eyes, signifieth a carnal man, a lover of songs and dances, and withal a great liar.

ON THE RELATION OF THE DISEASES OF THE KIDNEY, ESPECIALLY THE BRIGHT'S DISEASES, TO THE DISEASES OF THE HEART.[1]

By J. M. DA COSTA, M.D., LL.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AT THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA; PHYSICIAN TO THE PENNSYLVANIA HOSPITAL.

LECTURE I.

WHEN, by your kind thought, I was asked to deliver the Middleton Goldsmith lecture before your learned body, several subjects occurred to me which, from their great pathological interest, seemed worthy of the occasion, and which I believe the generous founder of these lectures would have approved of, could his cheery presence be here to animate us. From among these I choose, partly because it has been with me one alike of pathological and clinical investigation, the relation of diseases of the kidney, especially the Bright's diseases, to diseases of the heart. Much has been done of late years to examine this subject; but it is far from being clear or complete, and I must claim your indulgence if, in the endeavor to add a little to our knowledge of it, I allude to some facts which to you must be trite.

We all know that there is a close connection between diseases of the kidneys and diseases of the heart. But how intimate is this connection, and what determines it? Is there anything in an affection of the heart which would lead to a kidney affection? Or is the kidney disorder the starting-point of the undoubted combination observed? Again, are the lesions, when found together, both due to a common cause which determines them, and not the direct consequence of each other?

Allow me to detain you with a brief discussion of these weighty questions, before I call your attention to some of the finer points of pathological research which I shall attempt to demonstrate to you.

One of the first questions to solve is, Whether disease of the heart, in itself, leads to disease of the kidneys? The general impression is that it often, indeed generally, does. But on analyzing a large number of cases I find that this belief is incorrect. I will here give some of the results of my investigations into the matter, and will take the records of the Pennsylvania Hospital for a period of ten years, extending from the beginning of 1877 to the beginning of 1887, and similar records from the Clinical Department of the Jefferson Medical College for a period from June, 1875, to January 1, 1888, selecting merely the cases of which it was reasonably certain that the cardiac affection was the primary lesion.

At the Pennsylvania Hospital were noted of such cases of *valvular heart affections*, 76; at the Jefferson Medical College Clinic, of valvular heart affections, 51. Of these 127 cases, in all of which the urine was examined, for the most part repeatedly and at different times, and in many of which, especially in the cases at the Pennsylvania Hospital, autopsies are recorded, there were in 92, it is specifically stated, no evidence of any kidney affection, as shown by the absence of casts, of albumen, and, in a number of instances, by the notes of the post-mortem changes. The 76 valvular heart cases at the Pennsylvania Hospital furnished 28 cases in which some concurrent kidney affection was observed; the 51 cases at the Jefferson Medical College Clinic showed but 7. Of these 7, in 1 (Case III. of series), happening in a child with a mitral regurgitation, there had been scarlet fever three years, and an attack of rheumatism two years prior to the record of the case; there was hypertrophy with dilatation in connection with the valvular disease, and chronic parenchymatous nephritis. In another case (Case XIII.), that of a man fifty-two years of age, the mitral lesion, following rheumatism, was associated with urine one-fourth albuminous, and of character usual in parenchymatous nephritis. The dropsy began in the abdomen, the swelling there preceding that of the feet and legs for nearly a year. In the third case (Case XXV.), a presystolic mitral murmur was found with hypertrophy of moderate degree, but with considerable dilatation. The heart's action was irregular, the urine was full of albumen, and attacks of cardiac asthma and occasional uræmic convulsions occurred. In the fourth case (Case XX.), a married woman, twenty years of age, there was some abdominal dropsy and a puffy face. The valvular lesion consisted in aortic regurgitation with a slight mitral regurgitation; considerable hypertrophy of the heart existed. The pulse was 128. The urine was free from sugar, of specific gravity 1.018, and contained small amounts of albumen. The kidney was considered to be in a state of parenchymatous inflammation.

Of these 4 cases, in all of which, probably, the kidneys were in a state of chronic parenchymatous nephritis, the first ought really to be excluded, since the kidney affection much more likely had its origin in scarlet fever, leaving thus only 3 undoubted cases.

In 3 more of the series albumen is mentioned as occurring in very small quantities. In one (Case XVI.), it was present without tube casts; in another (Case XXXI.), where a mitral presystolic murmur as well as an adherent pericardium existed, a few hyaline tube casts were discerned in a feebly acid urine, free from bile and sugar, but containing a small amount of albumen and crystals of oxalate of lime. In a third, in which mitral regurgitation with considerable hypertrophy and dilatation was noted, albumen in small and varying amounts was detected, but nothing else. In all three instances it was due to congestion of the kidneys, and not an evidence of Bright's disease. We have then but 3 cases in 51 in which a kidney affection really existed.

I will now examine the 28 cases out of the 76 recorded at the Pennsylvania Hospital, in which the urine examinations indicated coexisting disorder of the kidneys. In 16 of the 28 the record speaks specifically of but small amounts or of traces of albumen and of the absence of casts. In one of these (Case I.), the autopsy tells of kidneys showing no marked alteration of structure except that, weighing respectively six and seven ounces, the capsules were thickened, and the right kidney contained two small cysts. The highest amount of albumen recorded in these 16 cases is one-sixth of the test-tube, sometimes one-tenth, and often the merest trace.

In 6 cases (Cases II., XVI., LV., LXIII., LXIX., LXXVI.), tube casts are described in addition to the albumen. They were hyaline or slightly granular casts. In 2 of these 6 cases we have autopsies; and this is a summary of the record. In one (Case LXIII.), the hypertrophied heart weighed thirty-six ounces, there was marked insufficiency from contraction of the aortic leaflets, slight thickening of the mitral; the kidneys were congested. cyanotic, otherwise normal. In the other (Case LXIX.), the heart weighed fifteen ounces; the mitral and aortic valves were both thickened. The kidneys were congested, but not altered in structure.

---

[1] The Middleton Goldsmith Lectures. Delivered before the New York Pathological Society, April 18, 1888.

In 6 cases the clinical record is that of much more serious disease. But one of these (Case LXV.) we must at once exclude, as the albumen, the pus, the epithelium, which existed in connection with the mitral disease was clearly of vesical origin, and any renal implication was most doubtful. Five cases of marked renal affection, with highly albuminous urine, we still have to account for. Of these, in one (Case LXI.), there were also pus cells and bladder epithelium; but distinct renal casts were detected, and the case was looked upon as one of parenchymatous nephritis complicating mitral insufficiency. In two (Cases XLII. and LIV.), the same view was taken of the renal complications, associated in Case XLII. with mitral narrowing; in Case LIV. with both mitral and aortic insufficiency. But in this case, in which highly granular and hyaline casts abounded, and in which the albumen was in bulk two-thirds of the test-tube, the conclusion is vitiated by the patient having been a great drunkard, and all his tissues having been profoundly altered. Case XLVII. is very instructive on account of its clear history. It happened in a man who had rheumatism thirteen years prior to admission into the hospital, but in whom dropsy and puffiness of the face only appeared two months before. The urine contained albumen, granules, and fatty casts. The greatly enlarged heart weighed, with clots, thirty-six ounces; without clots, thirty-two ounces. The mitral orifice readily admitted four fingers, so did the tricuspid orifice; the aorta was fully twice as thick as normal, but the aortic valves were competent. The walls of the right auricle were double the natural thickness; the left ventricle, its cavity enlarged about one-half, had walls measuring near the base one inch. The kidneys were engorged, and appeared in the early stages of parenchymatous nephritis. The left kidney, weighing twenty-four ounces, contained a few cysts on the surface; its blood-vessels were prominent, but not thickened. The right kidney was about the same in size and structure.

In Case LXX. we also have an autopsy. The aortic and mitral leaflets were thickened and contracted. The kidneys were large, firm, harder than normal, and evidently diseased, but showed no adherent capsules or signs of contraction.

Summing up the whole inquiry, we find in 127 cases of valvular disease of the heart but 8 in which any true affection of the kidney existed—anything more than mere congestion. And among these 8, there is not one instance of the contracted or cirrhotic kidney. In truth, the kidney disorder that results from a valvular disease of the heart is simply a congested kidney of full size, redder, a little more glistening, and in elderly people, or where the congestion has been of long standing, firmer than normal, showing even slight increase of fibroid texture, and, perhaps, a rather more adherent capsule. Persistent engorgement of the renal veins gives the well-known livid, cyanotic appearance to the somewhat indurated organ. The epithelium of the tubes is swollen, and finally undergoes granular degeneration.

I have, by the analysis of the cases, endeavored to give you a proof how rarely valvular disease of the heart leads to chronic disease of the kidneys, other than congestion. When it does, the form of affection is that of a chronic congestion, which, in its turn, passes into a parenchymatous nephritis. The granular contracted kidney does not, I believe, result from the process of congestion just alluded to; though, as I have already said, occasionally, especially in elderly people, the kidneys from long-standing congestion may appear hard, and exhibit a slight amount of fibroid change. These statements seem at variance with those of one of the most eminent of your members, Dr. Delafield,[1] who, in 137 cases of death from heart disease, reports 27 large white kidneys, 29 atrophied kidneys, and 28 of chronic nephritis which could not be classed as either large white, or atrophied organs. Perhaps the apparent discrepancy is to be explained by the cases being heart disease of which it was not specifically known whether it preceded the renal affection or followed it.

During life it may be very difficult in individual cases to determine whether we have, as the result of the heart malady, simply a congestive condition of the kidneys, or real Bright's disease; in truth, as in both states dropsy is a prominent symptom, we obtain but little aid from the general symptoms, having to base our opinion largely on an accurate cardiac investigation. It may be thought that the urine would afford us much assistance; but this it does not always do. A good many of my observations, in purely cardiac cases, speak of urine of low specific gravity, scanty, containing traces of albumen, and here and there casts. The character of these casts is, for the most part, epithelial and not highly granular, though this, too, must not be taken as an absolute rule. On the whole, the most important diagnostic sign, with reference to the urine, is found in the slight and varying amounts of albumen and in the infrequency of the casts. Moreover, though it has been stated that the urine, in even these heart cases with renal complication which is not Bright's disease, may have a low specific gravity—in one of my cases it was only 1.006—as a rule, the specific gravity of the scanty urine is high, ranging from 1.020 to 1.024; in one instance of mitral disease my record speaks of 1.030. Sugar was examined for, but found only once (Case XXII. of the Jefferson Medical College series); here there was aortic regurgitation. Urates, my notes say, are often abundant; biliary coloring matter is not infrequent.

The character of the pulse, the absence of marked arterial tension, and the precise physical signs of the cardiac disease, give us more valuable diagnostic evidence, taken as a whole, than the state of the urine. We may also lay stress on the want of uræmic symptoms, and avail ourselves of the ophthalmoscope as a means of diagnosis. It has, in fact, happened to me several times to determine, by finding albuminuric retinitis, the true meaning of the renal change and the secondary nature of the valvular affection. In one of these instances, indeed, albumen was at several examinations absent, tube casts were but few, the specific gravity was, as a rule, low; but the whole progress of the case, the uræmic symptoms which arose, the absence of dropsy, showed, irrespective of the eye appearances, that the renal malady was the preponderating and original affection.

Before proceeding, it may not be without interest to point out that the most common form of valvular disease, associated with renal disorder of the kinds we have found to exist, is mitral narrowing. In 8 of the cases at the Pennsylvania Hospital it is noted only in 2 that the urine is free from albumen. In the cases in which a real structural affection, a parenchymatous nephritis, is developed, mitral stenosis has a preponderating influence. Next stands—for tricuspid disease is so rare that I have not data sufficient to judge by—mitral regurgitation. In uncomplicated aortic disease albumen and casts are very seldom detected in the urine; so seldom, that it is always a question whether a mitral complication is present when kidney engorgement is found.

Pure *hypertrophy* and pure *dilatation*, instances, therefore, of enlargement without valve affection, give us the same form of kidney derangement we have been studying. But with reference to hypertrophy, unless the cavities are at the same time decidedly stretched we do not find albuminous urine. Thus this existed in only 1 out of 10 cases noted at the Jefferson Clinic. In pure dilatation, urine albuminous in traces, indicative of congestion of the kidney, is more common. Still, it does not exist in the majority of cases; and I have known it not to appear until the last week of life, even though that life had been a burden for months, owing to the enormous dropsical swelling and the turgid lungs.

[1] System of Medicine by American Authors, vol. iv.

We have been studying diseases of the heart and the kind of kidney affections they induce, selecting for analysis cases where, from the history, or the post-mortem results, or from both, the record of the antecedent malady was clear. We now turn to diseases of the kidney and their combination with diseases of the heart. It is well known that this combination is a frequent one. We find diseases of the kidney associated with valvular disease of the heart, with hypertrophy, with dilatation, and with pericardial affections. In studying the subject I mean to draw conclusions only from instances in which, from the history as well as from the concomitant features of the case, we may fairly judge that the kidneys were the first, or, at least, simultaneously, diseased.

Let us examine the valvular diseases of the heart as they are found associated with affections of the kidney. I find, looking at the records of the Pennsylvania Hospital for ten years, from the beginning of 1877 to the beginning of 1887, that in 101 cases of renal disease in which the state of the heart is particularly mentioned, 41 cases have a concurrent valvular heart affection, and in 60 there is no such lesion. Of the total 101 cases, 57 are acute Bright's disease and 44 chronic. Of the 41 renal cases with valvular lesion of the heart, 29 are Bright's cases of the chronic type, and 12 are of the acute type. Of the 29 cases of chronic Bright's disease with associated valvular heart lesion, it is noticed that 13 have a preceding history of rheumatism. In 5 there is a positive statement of no preceding rheumatic history. In the other 11 cases nothing is remarked about rheumatism.

Of the 12 acute cases with concurrent valvular lesion, 3 cases have the record that rheumatism did not precede. In the other 9 cases nothing is said with reference to a rheumatic history.

Out of 29 cases of chronic Bright's disease with valvular disease, the age of the youngest was thirty-three years; 14 of the 29 were beyond the age of forty-five years; the oldest was sixty-five years of age.

Of the 44 chronic renal cases, 8 were examples of the large, white kidney. The ages of these 8 were from forty-eight to sixty years. One case had double mitral and aortic murmurs, and was preceded by several attacks of acute rheumatism. Of the other 7, nothing is stated about either the heart or a rheumatic history.

Of the 57 acute renal cases, in none are mentioned signs of cardiac hypertrophy without a valvular affection, nor, indeed, do the notes show that even with this complication was the heart enlarged.

In the notes of the Clinic of the Jefferson Medical College, in 21 acute cases of Bright's disease, 20 of which had marked dropsical symptoms, the heart was found to be normal in all but 4, 2 of which had had a previous history of acute rheumatism. In these 4 cases there were evidences of valvular disease without hypertrophy.

From an analysis of these observations it becomes evident that the character of the kidney affection, in combination with the valvular lesion in the heart, is, in the vast majority of instances, the contracted kidney. Next stands acute Bright's disease, where, also, we find valvular affections, but here without the hypertrophy so common in the first group. In the acute, the strong influence rheumatism exerts is very evident; nor is that influence lost in the chronic, where an unusually large proportion are associated with rheumatism—too large a proportion for us to assume that it is a mere coincidence.

Let us inquire what the state of the valve lesion is. It is chiefly an affection of the mitral valve, consisting in a thickening of the mitral, with here and there rough deposits. Next in frequency, but with similar pathological changes, we observe a lesion of the aortic valves, occasioning either aortic narrowing or aortic regurgitation. A further cause of the valve affection is seen in some of these cases to be due, I believe, to the hypertrophy of the heart forming part of the Bright's disease preceding some general thickening of the valve, though even this may be wanting. A stretching of the valve subsequently takes place, but insufficient to close the orifice in the enlarging heart. Thus the hypertrophy and the dilated condition of the cavities give rise to the valvular imperfection, rather than this to the enlargement of the heart. It is in this way that I explain some very striking and interesting cases of hypertrophy occurring in advance of the valvular lesion, which I have observed, and in which the autopsies showed simply this imperfect closure of the orifice with a slightly thickened mitral valve, and at times with shortened and more rigid papillary muscles.

I have known, but far less often, a similar state at the aortic orifice. The aortic disease that existed was due to the stretching of the valve, which, having reached a certain point, could go no further. This stretching, with the simultaneous thickening, produced an opening through which the blood flowed back. It is thus that we may have a valvular disease following hypertrophy with dilatation, rather as the result of this process, than the hypertrophy and dilatation as the result of it. If you ask me whether this is a common cause of valvular lesion in Bright's disease, I say it is distinctly not; it is very much less common than marked valvular thickening with degenerative change.

You see, then, that the valvular disease of the heart which occurs in diseases of the kidney may be of varying origin; chronic thickening, deposits, degenerative changes, coexisting rheumatic alterations, which have led to these changes, and, lastly, mere hypertrophy and dilatation, which, associated, perhaps, with slight valve thickening, or with rigid papillary muscles, in its turn leads to valvular imperfection. Omitting the last-named group, the ordinary valvular affections in the Bright's diseases are the result of the altered tissue nutrition of the valves and the degenerative changes which take place there, as they take place in both the large and small vessels of the body. They are favored to a greater or less degree by the morbid products which, from want of proper elimination on the part of the kidneys, circulate in the blood. It may also be a question whether, in part at least, the altered nutrition of the valve may not be due to affection of their nervous supply. The changes, the degenerative ones certainly, are favored by age. Yet we cannot assume that age is the important factor it appears at first sight; for the acute Bright's affections show also, as has been proved, a strong tendency to the implication of the valvular apparatus, and the acute affections are much more common in the young, or, at least, in younger people, than are the chronic affections. Let me further notice, once more, a point brought out in the analysis of the cases submitted to you, namely, the frequent existence of rheumatism. This may well produce the valve injuries at the same time that it leads to other changes in the body; and thus be a general cause, both for the valvular affection and for the disease of the kidney and of other textures.

Before ceasing to examine the aspect of the subject, I will call your attention to some purely clinical facts which must make us receive with caution many of the statements of coexisting valvular disease of the heart and of Bright's disease. It is often recorded that there was present a soft murmur, variously heard; in some instances at the apex, in others at the right base. Now these murmurs in Bright's disease are not the result of valvular affection. They come from the state of the blood; or they are simply murmurs from temporary perversion of valve action—what we might call functional murmurs. They are inconstant, they are soft, and they are not signs of valvular disease of the heart. You will easily see that the error is all the more readily committed because we have hypertrophy, with or without dilatation, as such a common attendant upon Bright's malady. Thus, the mere hearing of a murmur in the heart is not a sign of valve affection in Bright's disease, not even when there is coexisting hypertrophy. We have to take into account its persistence, its character, generally rough, the state of the second sound of the heart, and the fact that it may be heard in the axilla, and posteriorly near the angle of the scapula, to make clear that it is of organic type, and not of the temporary character just referred to. Bearing this in mind, we shall have to reject a great many of the cases of so-called valvular disease of the heart, often loosely reported, in which the only evidence of the valvular affection is based upon a murmur, the particular character of which is not stated; or its softness or temporary nature is alluded to, but an erroneous conclusion is drawn from its existence.

The difficulty does not exist with reference to diastolic murmurs, which, in my experience, are always organic. But it is not lessened by a study of the pulse, which is in itself altered by the arterial lesions of the Bright's malady and by the thickened left ventricle; nor can we place, for similar reasons, much dependence on sphygmographic tracings.

I think, then, that the number of cases of valvular disease of the heart, existing as a complication of Bright's disease, is more often overstated than understated. Indeed, with the greatest care, unless the case has been for a long time under observation, it may be almost impossible to detect the true relation between the maladies. Much of the difficulty will be, however, solved, if we accustom ourselves to look upon them as not dependent upon each other, but due to a common cause, working almost simultaneously, or even at different periods—mischief in kidney, heart, and other textures. To the frequent starting of this common cause in rheumatism, attention has been called.

Let us pass to an examination of the *hypertrophy of the heart* which exists in combination with Bright's disease of the kidneys; I mean where the hypertrophy, with or without some dilatation, is a pure process, and not complicated with valvular disease. With reference to the acute cases of Bright's disease, I have already mentioned that we do not find hypertrophy. In the 22 cases of this character at the Jefferson Clinic, and in the 57 cases at the Pennsylvania Hospital—therefore in 79 cases—in most of which there was marked dropsy, in not one were the signs those of hypertrophy, not even in the instances with valvular lesion. A few doubtful exceptions are observed in the notes where strength of impulse is mentioned; but in these it is probable that the valvular affection which coexisted had its origin in a previous attack of rheumatism.

Thus, then, we may assume as positive that hypertrophy of the heart does not occur in acute Bright's disease. This is vastly different in the chronic form of the malady. Here, as is well known, hypertrophy is the rule. This subject is a matter of such common observation that it scarcely needs re-enforcement by figures; but I will quote, since they are based solely upon post-mortem records on a most extensive scale, the recent researches of Goodhart in "Guy's Hospital Reports" for 1886.

In the ten years from 1873 to 1882, inclusive, there were autopsies of 344 cases of granular kidney, and of 196 of chronic parenchymatous nephritis. The weight of the heart in the cases in which the kidneys were described as granular was in only 103 under twelve ounces, which was, therefore, within the limits of average weight. In 226 it was above this weight. Making allowance for all possible exceptions, as old age and wasting disease, and adding 36, which were hypertrophied hearts, though of average weight, there are 262 cases of marked hypertrophy in 329 undoubtedly granular kidneys.

After making all deductions for the cases of chronic parenchymatous nephritis, there were in 25 only a heart of average weight; in 119 there were hypertrophy of the left ventricle, a proportion of over one to four. In lardaceous disease of the kidney, hypertrophic changes in the heart and arteries were not observed, which agrees well with the general observation on the subject.

Dilatation of the heart becomes associated in a more or less marked degree with the growing muscle. It affects pre-eminently the left side of the heart. In Goodhart's paper, just quoted, I find 51 cases of notable dilatation of the left ventricle associated with hypertrophy in the 344 cases of granular kidney, and 33 cases in the 196 cases of chronic parenchymatous nephritis. It would therefore appear that the dilatation predominates in chronic parenchymatous nephritis, while pure hypertrophy does so in granular kidney.

In cases of hypertrophy, such as I have described, the heart attains very great size; the muscles are firm; for the most part it is a pure hypertrophy, only here and there there takes place some increase of the fibrous texture, as well as of the muscular. The muscular fibres are a little more opaque, and sometimes more granular than normal. As the disease advances, secondary degeneration, granular and fatty, may occur; but they do not happen unless there be decided coexisting disease of the vessels.

The state of the vessels in these instances of hypertrophy is very interesting to note. They show the same condition which has been found in the kidneys, in the brain, in the spinal marrow, in the lungs, and in many other parts of the body.

The inner coat is thickened, the muscular coat hypertrophied, the outer coat in a state of fibroid change, and the whole lumen of the vessel greatly lessened by these encroaching lesions. This lessening of the calibre is the same, as are the changes the same that we find in the renal vessels, and it may take place to a very great degree. My colleague at the Pennsylvania Hospital, Dr. Arthur V. Meigs, has recently shown me a section of a heart, obtained from a man under his care who died of granular kidney, with aortic valve disease, and left ventricle from three-fourths of an inch to an inch thick, exhibiting besides increased muscle beginning interstitial change. Microscopically examined, the first ascending branch of the left coronary artery was so much thickened, chiefly by the increase of the intima, that the lumen of the vessel was a mere chink, the thickening being irregular, about four times more on one side than the other.

You will readily see how such a state of things might lead to secondary degeneration by cutting off the blood supply from the hypertrophied muscle; and it is most likely that these degenerations which we have in the hypertrophied hearts of Bright's disease, which, however, I believe, are not the rule, come on as an after-result of the altered vascular supply.

As a few minutes ago I called your attention to some points of diagnosis with reference to valvular disease in Bright's affection, I may now call your attention to some points with reference to hypertrophy. It is not always easy to make this out clinically. We have to consider not only the size of the percussion dulness, but the extent of the impulse, as well as its force and position; the lowered apex-beat, which is often felt on a line with or beyond the nipple; and the heavy character of the first sound. Nor must we fail to take into account the character of the second sound, its accentuation at the base, which commonly happens in these hypertrophies in connection with renal change. Strong, extended impulse, displaced apex, altered sounds, and increased percussion dulness are the phenomena by which we judge; but not by any one of these alone, certainly not by the impulse, which may be temporarily increased by other causes than cardiac hypertrophy. On the whole, I lay most stress on the altered character of the sounds of the heart, both at the apex and the base, and the changed position of the impulse.

The enlargement of the heart which takes place in Bright's disease of the kidney may be made use of in prognosis. We are often greatly at a loss to form an opinion as to the probable length of the case and to the way in which it is progressing. Up to a certain point the occurrence of dropsy and of eye changes will assist us, as well as the evidences of marked arterial tension. But dropsy, while common in chronic parenchymatous nephritis, is very generally absent, or but slight, in cirrhotic kidney.

The urinary examination does not always afford us much light, for some of the worst cases are those in which—I allude especially to the cirrhotic kidney—the amount of albumen is small, or often temporarily absent, and in which the tube-casts are few; nor can we lay too much stress on the character of these casts. It is under these circumstances that I think the heart condition becomes an especially valuable means of prognosis. Where the heart is but slightly affected there will be reason to believe that the case will continue for some time, provided we do not observe signs of uræmic poisoning. Where, on the other hand, the hypertrophy is marked, there is ground for the fear that the disease is more general, is advancing, and that the case will not belong to those long cases of the affection which we sometimes encounter. Thus the study of the heart may be made use of as a means of estimating the amount of general change and the likelihood of shorter or longer life.

Let me reiterate the view that, according to my experience, the hypertrophy in the majority of instances is a pure hypertrophy, unconnected with degenerative changes. It is certainly so in the earlier stages of the affection. In instances of long-standing disease and in elderly people these degenerative changes may be found in the progress of the case; but my observations do not at all agree with those of Buhl, who has stated that fibrous and chronic interstitial myocarditis is very frequently found in connection with the hypertrophy. To its occasional occurrence I have already alluded.

Dilatation of the heart, unconnected with hypertrophy, or at least predominating over the increase of the muscular walls, is extremely rare. When it happens, it is the latter kind of cases, namely, beginning as hypertrophy, but the rate of increase of the muscular structure not remaining in proportion to the dilatation of the cavities that is met with. Among the cases at the Jefferson Clinic I have collected some instances of what might be fairly called dilatation unaccompanied by hypertrophy, or attended only by a slight degree of hypertrophy; and I have seen a small number in private practice. Goodhart points out that in the young the risk of dilatation of the heart is much greater than in older persons.

Another lesion of the heart which we observe in connection with Bright's disease, both acute and chronic, is *pericarditis*. But inflammation of the outer membrane of the heart forms only part of that general tendency to serous inflammation which we find in Bright's disease. It is probably due to the contaminated state of the blood, and neither its occurrence nor its explanation need here detain us.

Of all the heart affections passed in review, hypertrophy is the most common. Let us look at its cause. I leave out of consideration those cases where clearly existing valvular disease may have led to the hypertrophy; though even here it is always questionable whether some of the increased growth be not due to other causes than the valvular affection, and may not have preceded it. I will take the pure instances of hypertrophy and ask, How are we to explain them? It will serve our purpose best if, in considering this much mooted and most intricate subject, we give a short summary of the different views held as to the cause of the hypertrophy, rather than attempt an historical review of how and by whom these views have been brought forward.

One of the main views entertained is, that the hypertrophy of the heart is due to the blood contaminated by renal excrementitious matter, exerting a stimulating effect upon the action of the heart, thus leading to hypertrophy of the ventricle; and, further, that the impure blood requires greater force of ventricular contraction to propel it through the unwilling vessels. This view has the great authority of Bright, and is to this day advocated by some eminent teachers.

A second view, while taking note of the influence of the impure blood, holds that the altered blood tension produced by the disease of the kidney, and the difficulty of the blood circulating through it, give rise not only to the well-known feature of heightened arterial tension, but to increased size of the heart to overcome the resistance of the renal organs. This is largely the view of Traube and some of the German investigators, and has been recently reaffirmed by Cornil.[1]

A third view is that the left ventrical beats with augmented force because the arterioles refuse to receive the altered blood, and in consequence of the resistance these vessels hypertrophy, especially in the arterial coat. To overcome this muscular resistance, the heart has to act with greater force, and its muscles increase. This is, in the main, the view of George Johnson, and is largely based on that change in the muscular coat of the arteries which he has so well described.

A fourth view is that a fibroid degeneration, a fibroid overgrowth of the outer coats of the arteries, takes place over a large portion of the vascular system. In consequence of this, the heart has to struggle to overcome the resistance of the permanently narrowed vessels, narrowed by these hyaline, fibroid changes; and the enhanced blood-pressure shows not only in the raised arterial tension, but the increased resistance leads also to cardiac hypertrophy. This is mainly the view of arterio-capillary changes, of a vascular fibrosis as the cause of hypertrophy of the heart, which has been strongly and ably advocated by Gull and Sutton.

The last two views have much in common, at least as regards the production of the hypertrophy in consequence of the altered condition of the vessels.

I will mention a fifth view, which for the present I shall simply indicate, namely, that the hypertrophy, as well as to a great extent the vascular changes, are the result of a common process which takes its origin in the ganglionic nervous system. This is the view which in its main features flows out of some researches made by Dr. Longstreth and myself, and which here I simply state, intending presently to call your attention to the particular facts bearing on it.

Now, analyzing these different views, let us first take notice of the assumed influence of impure blood, and it is for practical purposes possible at the same time to examine into the supposed alteration of the blood-pressure due to the resisting kidneys. These views which I thus group together seem to me untenable. If true, why should we not have hypertrophy of the heart, and especially the form of hypertrophy far the most common, of the left ventricle, in other diseases of the kidneys than Bright's disease? Why should not, too, in the acute form of this malady, the heart be increased? It might be objected to this argument that, in the acute affection, the disease does not last long enough to produce muscular increase; but the objection will not hold good with reference to the other diseases of the kidney, in which serious, we might even say destructive, kidney lesions take place, in which uræmic symptoms happen, yet in which there is no cardiac hypertrophy. I will take the instances, a number of which have come under my observation, of persons dying from extensive cystic degeneration of the kidneys, in whom the heart was found absolutely normal.

Here is one. In a gentleman whom I attended, with a very large tumor in the abdomen, and who passed bloody and albuminous urine, there were for three weeks before death most marked uræmic symptoms. At the autopsy both kidneys were enormously enlarged, measured each about fourteen inches in length, were filled with cysts, and no trace of renal structure could be detected. It was, indeed, difficult to understand how life could have lasted so long with such extreme disorganization; yet the heart was absolutely healthy.

In a second case, the kidneys measured six inches in length, nearly four in width, and three and a half in thickness. The tissue was almost wholly converted into cysts, from the size of an egg to that of a pin's head. There was no disease of the heart. This specimen is now in the Museum of the Pennsylvania Hospital.

---

[1] Compte-Rendu du Congrês International, tome i. Copenhagen, 1886.

In a third case the two kidneys were greatly enlarged, irregular in outline, the capsule was roughened by shreds of inflammatory adhesions; the organs, measuring each about seven inches in length and four in width, were filled with cysts. The thoracic viscera were in an absolutely normal condition. The liver was found to be highly fatty. The kidneys are also in the Museum of the Pennsylvania Hospital.

I shall cite two more cases, partly to sustain my view, and partly on account of the evident uræmia which preceded death. A man, under forty years of age, by profession a gambler, was admitted into the Pennsylvania Hospital in a comatose condition. He had been struck at by a companion, while drinking in a saloon, but was not hit. Immediately afterward, to the astonishment of those around him, he fell to the ground unconscious, and remained in this condition until death, a day or two later. No history of his previous state of health was obtainable, further than that he had seemed well, and was nightly occupied at his business as a dealer in gambling games. The urine was found to contain some albumen, and a large amount of sediment, mostly of a cellular character. Death occurred in the hospital with all the signs of marked uræmia. The urinary secretion was extremely scanty, and the unconsciousness profound.

The circumstances connected with the death led to the arrest of the companion who aimed the blow; but the investigation of the coroner showed that death was due to natural causes, and not to violence. At the autopsy, the kidneys were found to be in an advanced state of cystic degeneration. They were greatly enlarged in all directions, and the tissue was almost entirely converted into cysts. The disease had evidently been of long duration. The lungs were normal, so was the heart.

Yet another case. A young servant-woman, who had been in good health so far as known, fell on the floor while engaged at the wash-tub, and was found lying in an unconscious condition. She partly regained consciousness, but, on her admission into the hospital, could give no satisfactory history. She died a few days later in a comatose state, with every evidence of uræmia. The kidneys showed advanced cystic degeneration. The heart was normal, and no lesions were presented in the other organs, save congestion of the lungs.

I have thus presented to you five cases leading to death with the most advanced cystic degeneration of the kidneys existing, with the blood evidently impure, and, finally, occasioning, in the majority, marked uræmic symptoms, yet with actually normal condition of the heart.

I might go further in this line of argument, and call your attention to the enormous kidneys with calculi embedded in them, kidneys which produce abdominal tumors large enough to be mistaken for gastric and omental cancers, also leading to death, and in which no disease of the heart was found; so, too, in instances of cancer of the organ; though, in this condition certainly, and even in cystic degeneration at times, the argument is somewhat vitiated by the fact that, while one kidney undergoes extreme change and disorganization, the other may remain normal, or, at least, be still capable of performing its function fairly well.

The next views, those of arterial changes, whether in the muscular coat producing muscular hypertrophy, or from fibroid growth in the outer coats, I shall not discuss, further than to say that I believe the anatomical researches on which they are founded to be correct, having often seen the conditions referred to. Nor is it necessary to go into the question which is the most common of these changes; for I think that both may be found in different cases, and even in the same case at different stages. While thus concurring in the correctness of these observations, I will point out how insufficient they are to interpret the cardiac hypertrophy; how impossible it is to prove that blood is resisted by the altered vessels on account of its character; how difficult it is to explain the enlarged heart simply as the result of vascular changes, when we have striking alterations in the vessels, both large and small, in old age, and from syphilis, and in and beyond aneurisms, where we do not find cardiac hypertrophy happening as rapidly, or to anything like the extent that it does in Bright's disease, if, indeed, it happen at all.

Let me now, before taking up the fifth view, which I told you had grown out of observations by Dr. Longstreth and myself on the nervous ganglia, call your attention briefly to these observations, and supplement them by some which have not hitherto been published. Let me add, and here acknowledge, that in the researches about to be brought forward, which were most difficult and laborious to carry out, it is to the care and attention of Dr. Longstreth that they owe their merit, rather than to anything I have myself been able to do. Let me also recall that in the investigations we made on Bright's disease[1] we found marked changes in the renal ganglia, of a character showing increased fibrous tissue and atrophy of the ganglion cells. These were associated with decided alterations in the renal vessels, as exhibited to you in these micro-photographs, which will make the matter clearer to you than I can from description. This condition in the renal ganglia has been confirmed by Saundby,[2] who, however he differs with our conclusions, has seen exactly the same pathological lesions.

I shall proceed to present to you the statement based upon 11 cases accurately observed, in which the cervical ganglia from which the cardiac nerves arise were minutely examined; and 5 of these cases, which tell the tale of all, I will give you in some detail. The records relate particularly to the inferior cervical ganglia, giving off mainly the inferior cardiac nerve. All of the cases were interstitial nephritis; 9 were chronic contracting kidneys, and 2 contracting kidneys of more acute form.

CASE I.—Emma H——, aged sixty-five, admitted into the Pennsylvania Hospital May 18, 1885; died May 18, 1885; admitted for cerebral hemorrhage; had vomited; was unconscious, and completely relaxed or paralyzed; had a few irregular convulsive movements; two quarts of highly albuminous urine were drawn by catheter; she died in three hours. Post-mortem examination showed an extravasation of blood in the external part of the left hemisphere, but it had not extended to the ventricles. Death resulted in this case apparently from uræmia, rather than from the cerebral clot directly. The kidneys were very much reduced in size, with thickened capsules and granular surfaces, dotted with small cysts. The left ventricular wall was much thickened, measuring over one inch. The minute structures of the inferior cervical ganglion showed many marked changes; the ganglion cells were deeply pigmented, appeared shrivelled or compressed; equally to be noticed was the tissue around the ganglion cells, composed of a delicate fibrillar tissue in which appeared very numerous round and spindle nuclei. Some of these nuclei were doubtless those of the nerve structures, but the majority were a new growth of connective and fibrillar elements; in places they were so numerous as to obscure the ganglion cells. In the greater part the vesicular nucleus of the ganglion cells could be seen, but the nucleus was generally visible, faintly stained with carmine. A very striking feature was the appearance of the vascular structures; in the first place, the capillaries seemed in some parts to pervade nearly the whole area, some with a narrow calibre carrying but a single red blood-corpuscle, and from this width upward to those with six corpuscles abreast, and many of these vascular tubes presented ampullar dilatations; some of this condition can be accounted for by the mode of death, but the most was due to permanent changes. The walls of the arterioles showed the thickening so often found and described in the arterial walls in these cases of renal disease.

---

[1] American Journal of the Medical Sciences, July, 1880.

[2] British Medical Journal, January 13, 1883.

CASE II.—Hannah G——, aged seventy, admitted September 4, 1884. No. 920. Died November 13, 1884. Had been gradually failing in health, and lately had chest symptoms and œdema; the secretion of urine had slowly diminished. On admission there was orthopnœa, the lungs were full of coarse râles, and were emphysematous, rendering any accurate determination of the size and condition of the heart impossible. The apex of the heart was far to the left of the normal. There was ascites, and also diarrhœa.

The heart showed hypertrophy of the left ventricle, its tissue was undergoing fatty changes and atrophy; the kidneys, although much altered, did not exhibit the marked changes of the other cases. The minute structure of the inferior cervical ganglion cells indicated atrophic conditions; the cells were pale, with less than the normal amount of pigment (as usually seen in the ganglia of adults dying of disease), the nucleus was plainly visible, but the nucleolus stained with carmine very faintly. Between the ganglion cells the tissue was of firmer character than normal, and appeared to encircle these cells with stiff fibres. There were no round nuclei, but only flattened spindles in this space. The capillaries were not conspicuous, but the walls of the arterioles were altered, though to a less marked degree.

CASE III.—Mary McG——, aged fifty-two, admitted November 3, 1884. No. 1,288. Died January 30, 1885. Her history tells of a severe cold, followed by swelling of the legs; urine of dark color and much reduced in amount; later, nausea and vomiting. On admission, the urine was smoky and contained fifty per cent. of albumen; the microscope showed blood, hyaline, and granular casts, and also some epithelial casts. Only twelve ounces of urine were passed in twenty-four hours. Dyspnœa and diarrhœa existed. Later came uræmic convulsions and strongly urinous odor of the breath and body. Post-mortem examination: Heart weighed sixteen ounces; right distended, left contracted and much hypertrophied. Liver small, pale, and granular. Kidneys reduced in size, firm, capsule adherent, and the surface granular. The case was an acute attack of nephritis in a contracting kidney.

The microscopic examination of sections of the kidney of this case was very interesting, showing the majority of the Malpighian bodies converted into firm fibrous nodules, and only in a few places were the convoluted tubes to be seen. Here and there a Malpighian body presented somewhat of a normal aspect, with a few tubes around it, in which the epithelium could be distinguished. The chief feature was the fresh outpouring of small indifferent cells, as seen in acute interstitial nephritis. The ganglion cells were in an advanced state of degeneration, full of granules, shrivelled, and the nucleus and nucleolus scarcely to be distinguished. Between these cells the tissue presented a fibrous aspect.

CASE IV.—Rose B——, aged thirty-seven, admitted December 13, 1884. No. 1517. Died January 12, 1885. The attack followed gradually after pregnancy, with greatly diminished urine secretion—one-half teacupful in twenty-four hours. Diarrhœa and swelling of abdomen were noted. The lungs were full of râles, and the pleural cavities contained effusion. The heart-action was rapid, the pulse "corded," the artery hard. The urine was albuminous and contained granular casts. Post-mortem examination: Pleural and abdominal effusions; old pericarditis; hypertrophy of the left ventricle, the wall measuring one and a half inch; liver showed cicatrices, possibly syphilitic; kidneys very small, the capsule thickened, the surface highly granular, the cortex had almost disappeared, while the cones were much distorted.

The inferior cervical ganglion presented even more highly altered conditions than in the previous case. In not a few instances the cells seemed to have nearly vanished, or a few grains of pigment evidenced their site. Other cells, while showing some pigment, looked blurred, shrivelled, and irregular in outline. The nucleus was misshapen, and the nucleolus was like a fragment of poorly stained matter, pushed over to one side of the nucleus and attached to its wall. Around the cells the fibrous tissue formed circles, closely resembling the thickening of Bowman's capsules in a contracting kidney. Even the spindle nuclei in the tissue between the cells had lost their distinctness, and the fibres looked less firm and rigid, but coarser.

CASE V.—Mary H——, aged thirty-four, admitted January 4, 1885. No. 1647. Died January 8, 1885. For four months had had œdema, and for two days orthopnœa. The urine contained one-sixth albumen, and hyaline and granular casts. Death was sudden. Post-mortem examination showed old pericardial thickenings; weight, twenty ounces; the left ventricle measured one and one-half inch. The kidneys weighed each one and one-half ounce, capsule thickened, and tightly adherent; the surface was very granular. On section, the cortex had almost disappeared, and the pyramids were much distorted.

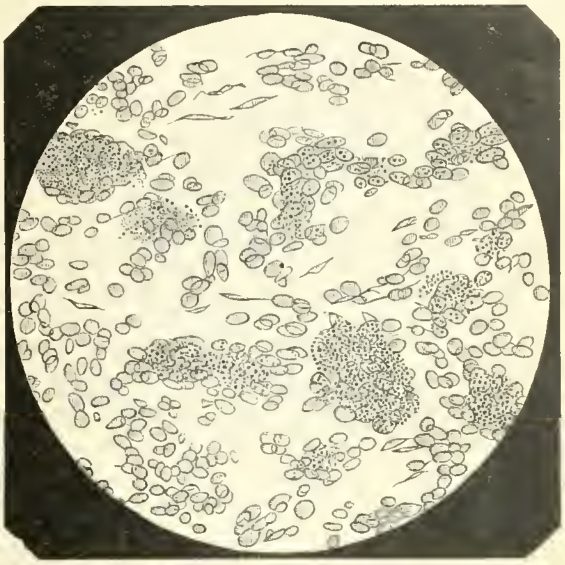

FIG. 1.

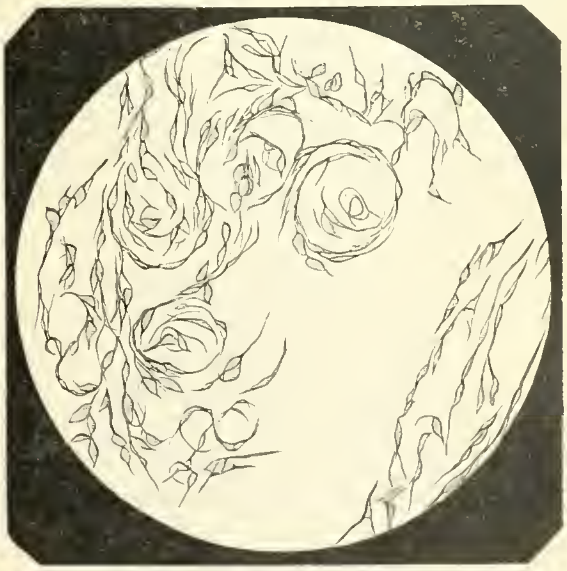

FIG. 2.

This specimen was less well prepared for examination than the others, owing to the delay in obtaining the autopsy; but however much the ganglion cells changed through the delay, this factor cannot account for the alterations of the tissue of the cardiac ganglion. The general conditions were the same, very nearly, as in the previous specimen.

I will not present to you any more details of cases, but will rather exhibit to you some microscopical drawings, taken directly from sections. Fig. 1 shows the ganglion cells treated with the ordinary carmine staining, highly granular and pigmented; their outlines indistinct; the nucleated nucleus scarcely visible. The texture between the ganglion cells is crowded with small, rounded, or spindle-shaped nuclei. These nuclei are specially numerous around and overlying the ganglion cells. The specimen is from a case in a moderately advanced stage of degeneration. Fig. 2 shows the lesion in a later stage. The whole tissue is firm and hard looking. The ganglion cells are surrounded by rings of coarse fibres, in which are a few remaining spindle nuclei. The ganglion cell itself has greatly shrivelled; the nucleus is pressed to one side, the nucleolus showing indistinctly. In some places the ganglion cells have wholly disappeared.

These, then, are the pathological minute lesions in Bright's disease in the ganglia regulating the heart movements. Before entering into the question of the bearing of the abnormal appearances, it may be well to answer the question: How does death come in the hypertrophied heart of Bright's disease? It comes with contraction of the left ventricle and dilatation of the right; in other words, it is a death of apnœa rather than one of asthenia. The diseased ganglia do not produce paralysis of the heart. As an instance of how even acute destruction of the ganglia will cause death, similar, as regards the heart, to that in Bright's disease, I cite the following case of injury and of hemorrhage into the cervical ganglia, the autopsy of which was most carefully made by Dr. Longstreth.

Thomas McC——, aged fifty, admitted into the Pennsylvania Hospital, February 1, 1882. The patient fell on shipboard, fractured the third, fourth, and fifth cervical vertebræ, and became immediately paralyzed, both as to motion and sensation, from the level of the second rib and deltoids downward; breathing was diaphragmatic; the pupils were contracted. There was priapism and retention of urine; the heart's action was frequent and feeble. Post-mortem examination showed large clots pressing on the cervical ganglia; at the third vertebra the cord was compressed and softened. The lungs were congested; the right heart was distended, the left ventricle firmly contracted. The microscopic examination of the ganglia, especially the inferior cervical ganglion, exhibited in many places the presence of extravasated blood around the ganglion cells; some of these cells showed already changes, especially pigmentation, although but a few hours had elapsed between the accident and death; in other respects the cells and tissue of the ganglion appeared normal. The kidneys were normal.

But to return to the examination of hypertrophy of the heart in Bright's disease. I have, I trust, made clear to you that there exist, associated with the enlarged heart, marked changes in the ganglia of the sympathetic nerve, from which the cardiac nerves are derived. Is it going too far to assume that these changes are an integral part of the disease; that they may determine the hypertrophy? How, I cannot explain to you exactly. It would not be difficult to bring forward a theory of loss of controlling influence on the heart, produced by the altered condition of the nervous apparatus; but our knowledge of the physiology of the nerve supply of the heart is not accurate enough to admit of absolute reasoning from cause to effect. Still, that disturbed nerve-power produces changes in structure by affecting its nutrition, we know, in every tissue of the body. Why should not the same be true for the heart? Again, if we adopt this view of the derangement of nerve condition and of the vaso-motor influence being the starting-point, we can readily explain the well-known lesions in the vessels, both large and small. Indeed, when we look at the wide-spread changes which occur in them in Bright's disease, especially in its chronic form; when we see everywhere accumulating the evidence that these changes happen in all the vessels of the body—in those of the spinal cord, the brain, the lungs, the liver, in veins as well as arteries—we are driven to the conclusion that there must be some general cause at work which determines so great, so universal an alteration. That general cause, from the nature of things, can only be in the blood, in the vascular system itself, or come from the nervous offices which give life to the vascular system. The change is too extensive to be a mere self-determined local growth of the coats of the vessels. We cannot, indeed, ignore the agency of the waste-laden blood in its full development. But what starts the change? What is the cause of the degeneration? Is it not fair to look, beside the blood, to a cause so predominant as the nervous influence, which is everywhere?

I would thus locate as most likely the original starting-point of the alteration, alike of the vessels and of the heart muscle, in the nervous ganglia and in the parts of the nervous system controlling the nutrition of these textures. What the ultimate cause of the lesion is cannot be stated, nor need we assume that one cause alone will determine it. It may be gout, it may be lithæmia, it may be rheumatism, it may be alcohol, it may be lead, it may be mere purely perverted nervous function from worry, from strain, from anxiety. Any one of these causes may start that alteration in the ganglionic nervous system which leads to degeneration and to the formation of increased fibrous tissue and subsequent atrophy to, and with it also the heart, and it is that change in the vascular textures supplied by the derangement of the heart and affected ganglia and nerve-filaments.

These are, of course, not matters that can be at once proved or adopted. You must take them as lines of thought which have come naturally from the investigations pursued, and which promise as rich a return as any that we have had from following out views hitherto brought forward. Whether the suggestions based on these researches prove to be correct or not, I think that the observations themselves furnish one more proof of the general character of what we call Bright's disease, especially in the cirrhotic form. They show us that the primary changes are to be looked for away from the kidneys, not in them, and that there is a general disease, based on a general wide-spread cause, underlying the vascular changes, heart atrophy, and kidney disease.

But to return from these reflections to the state of the heart in Bright's disease. Looking now at the result of all the observations and the process of reasoning by which I have endeavored to collate them; looking at the general pathological facts which have been cited, I draw this conclusion: That the cardiac hypertrophy which is found in Bright's disease is not in any sense the consequence of that disease. It is an integral part of the same general morbid process, of which the kidney lesion is only the most obvious expression. You may believe, with me, that it is in the nervous system that we are to look for the ultimate, or, it may be more correct to say, the original source of the malady. You may hold that this is not proven, that the changes there are only part of the general changes described, and are not the first; that they are result, not a cause. But I trust you will see how disseminated an alteration they indicate; how everything points to a general rather than to a local malady, and not think me too venturesome in stating that chronic Bright's disease ought not to be looked upon as an affection of the kidney at all, though it is there that, to the naked eye, its most pronounced changes occur. In adopting this conclusion, the cases that die of apoplexy from disease of the vessels of the brain before the kidney disease shows any signs; the cases with general vascular tension in which there is as yet no albumen or other signs of renal malady; the cases with marked, the cases without as marked, cardiac lesion, receive their ready explanation. They cease to be objects of wonder. The mischief wrought by the general malady has been wrought more elsewhere than in the kidneys. It may exist to a greater, it may exist to a less degree in any structure; it may be diversified in a very varying degree, and be present in parts in very alterable proportions.

These conclusions I draw more particularly from a study of the pathology of the contracted kidney. Perhaps it would be better to limit them to this condition, and to call this general malady Bright's disease of the kidney only until someone with a genius for names gives it one we can all adopt. There may, in fact, be some of the forms of the so-called Bright's disease which are really affections of the kidney; there may be deposits or degenerative processes in the kidney simply superadded to the textural changes in the contracted organ. These intricate questions cannot be here discussed; they are, indeed, with present knowledge, beyond our solution. But, examined in the light of the view which we have inquired into to-night; with each group of cases looked at by itself; with the structural alterations in other organs and parts than the kidneys, minutely inspected; with the condition of the blood-vessels everywhere, and of the nervous ganglia, noted; with the antecedent changes as far as possible considered, it may be then that other groups will stand forth separately as showing diverse general states as their basis.

No pathological research in these days of keen induction stands long by itself. No view can be even approximately proved, that we do not at once begin to search how, as practical physicians, we can make it available for the prevention or cure of disease. That the treatment of Bright's disease, and of what are regarded as its complications, is not what we wish for, is everywhere felt. If lines of investigation and of thought should lead to the recognition of the malady being a general rather than a local one, and discern its starting-point, lines of practice which are in accordance will be pursued, and it is by following these lines that helpful and hopeful results will, I believe, come. As yet, even with the wish to work in that direction, we may not have the exact agents for the purpose. But science now is too resolute to halt helplessly before obstacles when once the path beyond is clearly recognized.

PAPILLOMATOUS TUMOR OF THE BLADDER, DEMONSTRATED BY MEANS OF LISTER'S ELECTRO-CYSTOSCOPE.

Diagnosis confirmed Sby ubsequent Inspection through Suprapubic Opening of the Bladder—Successful Removal.

By F. N. OTIS, M.D.,

CLINICAL PROFESSOR, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

A. G——, aged twenty-three, United States; single; barber. Gonorrhœa at fifteen, followed by a gleet, which lasted nine months. After this, was entirely free from genito-urinary trouble for six years. He then became the subject of attacks of frequent and painful micturition, these coming on without apparent cause, lasting for a week or more, and gradually passing off until free from apparent trouble, perhaps for several weeks, when a similar attack would occur. There was no urethral discharge, but the urine was occasionally tinged with blood. The patient states that in October, 1887, he became a patient in one of our city hospitals, where he obtained prompt relief, from the use of naphthaline capsules and deep injections of nitrate of silver, and after fifteen days was discharged cured. His former symptoms soon returned, however, and he re-entered the hospital December 15th, where he remained until March 10, 1888, without marked benefit. During this period the bladder was explored by sound for stone by four competent surgeons, on four different occasions, with negative results. No abnormal condition was recognized during either examination. Both the frequency and pain of urination were increased, and also the hæmaturia. Occasional passage of small clots of blood. Microscopical examination of these, and of the urine, failed to reveal any evidences of morbid growth.

The young man was referred to me by his former medical attendant, March 16, 1888. His urine was found to be slightly but distinctly tinged with blood, and contained some small clots as well as some pus and mucus. He complained of exquisite pain on urination, increased at the close, recurring every half-hour. Through examination per rectum (*a posteriori*) unusual tenderness was found. Distinct increase in the density and thickness of the right inferior section of the bladder was recognized by the bimanual touch; a catheter was introduced, and three ounces of bloody urine removed. The bladder was then irrigated gently with a saturated solution of boric acid until the fluid returned clear. The catheter was then withdrawn, leaving about four ounces of the solution, of a temperature of 80°, in the bladder, as a preparation for its examination by the electro-cystoscope, of Lister. The required current was furnished by the small six-cell battery of the Galvano-Faradic Co. The cystoscope was then introduced into the bladder, and the current turned on. The illumination was complete. Through the slightly rosy medium the small blood-vessels in the bladder mucous membrane were distinctly seen. On the right side a deep-red, granular-looking mass, with a wavy outline, was then distinctly observed, covering about one-fourth of the cystoscopic field. This appearance was verified by Drs. Abbe, Bangs, and W. K. Otis—the unanimous opinion being that it represented a papillomatous growth, to some extent covered by coagulated blood. Two days later a similar examination was made, under the influence of an anæsthetic, which corroborated the previous observations in every particular. (See Illustration.)

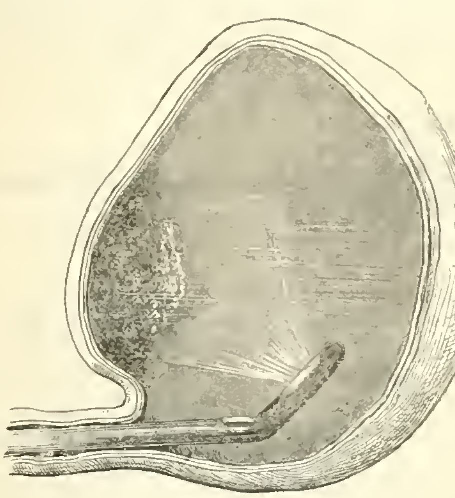

Fig. 1.—Diagram of Bladder, showing Location of Tumor and Position of Cystoscope.

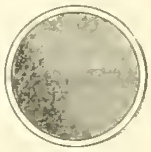

Fig. 2.—Appearance of Tumor through the Cystoscope. Apparent Size.

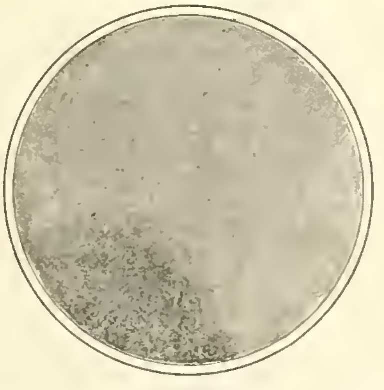

Fig. 3.—Real Size of Field Covered. Reproduced by photo-gravure process from the author's sketch.

Some small filaments were subsequently removed with the lithotrite, but on microscopical examination nothing of diagnostic importance was discovered. From lack of the capacity of the bladder, the field was necessarily limited; nevertheless, a very excellent view of the tumor could be obtained. This is shown in the illustration, from a sketch made at the time of the first examination—the smaller (Fig. 2) field representing that which was seen through the cystoscope, the larger (Fig. 3) representing the area of bladder-wall actually covered. Fig. 1 represents the position of the tumor and cystoscope when the best view of it was obtained.

On the following Monday the patient entered St. Luke's Hospital, and was operated upon by my associate, Dr. L. B. Bangs, Dr. Charles McBurney assisting. The high operation was performed, and the bladder being examined by means of an electric light, introduced through the suprapubic incision, the diagnosis made by the cystoscope was verified in every particular. The growth was then removed, as far as possible, with the scissors, and the surface cauterized with the Paquelin cautery. At the present writing the patient is going on toward a satisfactory recovery. The pathological examination made by Dr. Frank Ferguson, pathologist of St. Luke's Hospital, showed the neoplasm to be a simple papilloma.

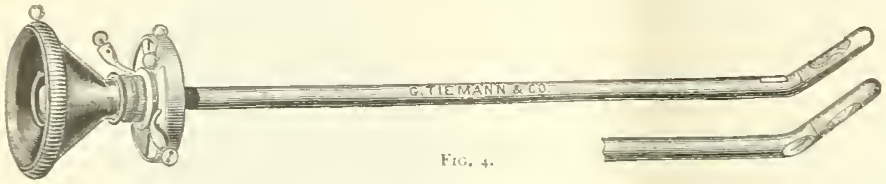

Fig. 4.

This case is deserving of especial interest as being the first tumor of the bladder diagnosticated in this country by means of the cystoscope, and verified by subsequent operation, and adds one more to the list of sixteen cases so made out by foreign observers, and two by Dr. Fenwick, of England. In this instance the instrument deserves particular credit, as other methods had completely failed in the practice of competent observers.

This consists of a metal tube (Fig. 4), about seven inches long, of a calibre of 22 French, having at the proximal end a funnel-shaped ocular opening; at the distal, a short beak, similar to that of the catheter coudé. A window of rock crystal is set in the end of this beak, behind which a small electric lamp, controlled by a switch at the ocular end, is placed. A rectangular prism, the hypothenuse plane of which is silvered, is placed in the end of the straight portion of the tube, its superior face being seen just anterior to the angle formed by the beak. The distended bladder is illuminated; by the electric lamp, the rays reflected from its wall falling on the prism experience total reflection, an inverted image being formed within the tube. The size of the field thus obtained is greatly increased by means of a telescope introduced into the tube. The image seen through the cystoscope is an inverted image, but right and left are not transposed.

There can be no question as to the great prospective value of the electro-cystoscope in diagnosis of many difficulties to which the bladder is subject. A variety of foreign bodies have already been reported as made out by use of this instrument. The locality, size, and color of vesical calculi have been demonstrated in my own experience. In one instance two stones were seen where only one had been previously found; but this, of course, might with care have been effected by means of the lithotrite. But it is in the diagnosis of the tumors, and encysted or impacted calculi, that the most essential service may be anticipated from the use of the cystoscope. The orifices of the ureters are quite readily brought into the cystoscopic field, and it is more than probable that (perhaps through the introduction of some clear fluid with which blood does not readily mingle—glycerine, for instance) the true source of a previously doubtful hæmaturia will be demonstrated.

5 West Fiftieth Street, April 30, 1888.

Dysmenorrhea in the most violent forms has been relieved by Meniere, by giving an enema consisting of bromide of potassium and chloral, thirty grains of each; one-half of this amount to young girls.—*Am. Practitioner.*

ON DIVERS SPECIES OF ITCH.

By GEORGE HENRY FOX, A.M., M.D.,

NEW YORK.

An editorial in The Medical Record of January 14th, calling attention to the subject of "winter itch," has elicited several interesting letters. In a recent number (April 14th) Dr. Leroy Dibble relates, in a graphic manner, his personal experience of this affection and the sufferings it has entailed. He incidentally mentions, with perhaps more freedom than delicacy, the names of several gentlemen whom he consulted, the opinions or prescriptions which they gave, and the lack of benefit derived therefrom. Lest the reader of his letter might erroneously infer that my treatment of winter itch consists of white precipitate and tar soap, I yield to the temptation of saying a word in regard to the doctor's case, and expressing some views upon divers species of itch.

Reference to my notes of cases shows that Dr. Dibble consulted me nearly four years ago in regard to some patches upon the scalp, and bearded portion of the face, which I pronounced to be eczema. For dry eczema in this locality, a good result will usually follow the use of tar soap and a daily inunction of the ammoniated mercury ointment, pure or diluted. I should not think, however, of recommending the ointment to be applied over a large extent of skin in winter itch, or any other affection, as I have repeatedly known salivation to result from its free use in cases of general eruption. I certainly did not prescribe it for winter itch in the doctor's case, and for the "relief" which he mentions I can therefore claim no credit.

As to the nature and treatment of so-called winter itch, much confusion appears to exist. I cannot, however, quite agree with your correspondent, who says, "We know nothing of its pathology, and as little about its treatment." In my opinion, the affection is a cutaneous pruritus, mainly of internal origin, although the action of extreme cold and variation of temperature upon the skin is prone to serve as an exciting cause. An unsuitable diet is a very frequent etiological factor, and I heartily indorse the opinion of the late Tilbury Fox, of London, as quoted in The Medical Record editorial, that pruritus results from a deficiency in the excretion of nitrogeneous matters and bile products. Imperfect oxidation of the food, resulting from overfeeding or lack of exercise, or from both, occasions the affection in a large proportion of cases, if not in all cases where no disease of internal organs is present.

Since the etiology of pruritus depends far more upon dietetic than upon meteorological causes, the use of the name pruritus hiemalis, as indicating a distinct affection, has always seemed to me to be unsound and uncalled for. In England, a summer pruritus has been described, and in certain localities conditions might readily be imagined to exist which would necessitate the addition to our nomenclature of spring and fall pruritus. A large proportion of skin diseases are much less frequent in summer than in winter, owing to an increased activity of the cutaneous glands, which tends to lessen the surface congestion. Psoriasis, for example, frequently disappears in hot weather, and is usually most pronounced from October to May. We might as well claim that cold is a cause of this affection, and add to our already burdened nomenclature a psoriasis hiemalis.

The reason that itching of the skin is apt to be more common in winter is due to several causes, of which improper diet is one of the most active, and cold one of the least important. Confinement in overheated and poorly ventilated rooms, and hugging a "glowing coal stove," especially after a hearty meal, is probably quite as conducive to pruritus as exposure to a blizzard.

The affection under consideration should not be attributed to uncleanliness or lack of bathing in any case. Nor can it be regarded as peculiar to any one stratum of society. It affects both rich and poor, and shows no preference for such as bathe daily, or for those whose ablutions are few and far between.

These views being accepted, the treatment of the affection is placed upon a rational basis, and my experience has taught me that, in the treatment of pruritus occurring in winter, far more can be accomplished by a modification of the diet than by all the remedies, internal and external, of the whole pharmacopœia. A man who suffers from an itching skin will often notice that the trouble is aggravated whenever he takes a little cold, or eats, drinks, or smokes more than usual, and, as a direct consequence, suffers from indigestion, or becomes constipated. I regret that his physician sometimes fails to appreciate these significant facts, and in his perplexity concludes to increase the dose of arsenic or to try a new ointment.

From my point of view, the indications for treatment are the following, and I would that all cases of cutaneous disease would yield as readily as do most cases of persistent pruritus when these measures are adopted: In the first place, see that the *primæ viæ* are open. Next cut off temporarily the supply of nitrogeneous food and increase the amount of water taken daily. Then stop alcohol, tea, coffee, and tobacco, the latter two being prolific sources of pruritus and capable of nullifying the good effects of almost any plan of treatment. Finally, if it is necessary, see that the patient gets an increased supply of oxygen by frequent exercise in the open air.

As for palliative measures, there are local applications which can be advantageously used to allay the nightly agony until the cause of the trouble is removed. A chrysarobin ointment, such as is mentioned in the letter of Dr. J. W. Foster, will always afford relief, unless it happens to occasion a dermatitis which may prove worse than the pruritus. An ointment containing twenty per cent. of resorcin is quite as efficacious, and far more satisfactory to the patient. A weak carbolic-acid lotion is usually disappointing, but two drachms of the pure acid to an ounce of glycerine and water, applied at night, will tend to anæsthetize the skin and grant to the patient a few hours at least of comfortable sleep.

In fact, any "mild cautery," like the saturated solution of chloral hydrate, mentioned by Dr. Dibble, will afford temporary relief, but it cannot be expected to have a curative effect.

What is prairie itch? Is it contagious? What causes it? What will cure it? These questions are frequently asked, and variously answered by those who know all about it and by some who evidently do not.

Of late years there seems to have been an epidemic of pruriginous eruptions throughout certain of our Western and Southern States, or, if the cases have not multiplied, the attention of physicians has been excited to such a degree as to cause much discussion and the firm belief on the part of many that a new form of skin disease is prevalent. I regret that I have not had the opportunity of studying this alleged new disease on its native heath, but, from all that I have read and heard, and from a careful study of the cases which have drifted East and come under my observation, I have arrived at a very decided if not a correct opinion as to its nature.

In the city of New York and its vicinity we have a number of pruriginous eruptions to deal with, and often the diagnosis in a given case is by no means easy to make. Those which seem to bear a resemblance to the so-called prairie itch may be classed as follows:

1. Scabies.
2. Pediculosis.
3. Pruritus cutaneus.
4. Urticaria.
5. Eczema.

I am strongly of the opinion that nearly every case of prairie itch belongs rightfully in one of the above classes. In this opinion I find myself in accord with Dr. Hyde, of Chicago, as expressed in the last edition of his excellent work on skin diseases. If in a given case there is distinct evidence of contagion, the disease is either scabies or pediculosis (or possibly contagious impetigo). If the eruption is manifestly non-contagious, it is probably pruritus (whether occurring in the winter or summer), or urticaria, or the papular form of eczema.

Scabies is a disease which is not always readily recognized by an examination of the patient's skin. In certain cases, where the hands are washed frequently with soap and water, the characteristic lesions upon the web of the fingers are absent, and the mistake is frequently made of declaring that a patient cannot have "the itch" because the hands are free from any eruption. In such cases the nature of the disease is usually suggested by the peculiar localization of the scratch-marks upon the forearms, lower portion of the abdomen, and inner aspect of the thighs. In women the excoriations are usually abundant upon the breasts. When a few red and excoriated nodules are found upon the glans penis, prepuce, or scrotum, we have a pathognomonic lesion and one which is almost as positive a proof of scabies as is the cuniculus or burrow of the insect. Having based a diagnosis upon the localization of the scratch-marks, this can usually be verified by the fact that several members of a family are simultaneously affected, and especially those who have been sleeping together. The acarus is noctambulistic in its habits, and rarely do we find a patient with scabies who has not slept with someone similarly affected, or in a bed which he or she has occupied. The cases of winter itch mentioned by one of your correspondents were doubtless, in large part, cases of scabies. This I infer from his remark that the eruption occurred upon the thighs, forearms, abdomen, and scrotum, and was conveyed from one bedfellow to another.

In Dr. Neely's paper in the *Mississippi Valley Medical Monthly*, the features of cutaneous pruritus are clearly presented, and the writer remarks that he has never seen a case directly traceable to contact or exposure to another case even though occupying the same bed.

Dr. J. E. Clark, in the *Medical Age*, has described a new skin disease characterized by a papulo-vesicular eruption and intolerable itching. The description given suggests scabies, and particularly the remark that it is contagious "unless the precaution of separate beds is observed." He differentiates it from scabies on the ground of the absence of the acarus. Now, in few cases of scabies is it an easy matter to discover the acarus, and frequently, when the patient has been scratching for several weeks, no unmistakable trace of the insect can be found.

Dr. H. J. Warmuth in the *Nashville Medical News* has described a contagious eczema as occurring not only in the West and South, but also in the Eastern States. He claims that the serum contained in the vesicles undergoes a change which favors the formation of parasites, and remarks that his patients traced their affliction to friends with whom they slept, or whose clothes they wore.

Dr. J. E. Engstad has attributed prairie itch to a vegetable organism found chiefly in the corium.

I have seen several patients from the West who brought with them a diagnosis of "prairie itch," and examination has shown that they were suffering from simple, unmodified scabies. There was nothing peculiar about the eruption, and it yielded as readily to sulphur-ointment as do the cases which develop beneath the seventy-fifth meridian.

Pediculosis is a disease which is especially apt to pass unrecognized when occurring in a mild form, and, as sometimes happens, in the person of an aristocratic patient, in private practice. A hungry pediculus may be readily picked up in travelling, and the unconscious host is very prone to attribute the itching of the skin which speedily ensues, to buckwheat-cakes, or woollen underwear, or a cold snap, or to anything but the true cause. The physician consulted in regard to the pruritus may not suspect the cause, or dare to reveal his suspicion by asking an offensive question or rigidly examining his patient's clothing; and so the diagnosis is made of winter itch, Rocky Mountain mange, or whatever name he may prefer. Two years ago a medical friend called and told me that he had just come from the meeting of the American Medical Association at St. Louis, where he had caught the prairie itch. I was delighted at this opportunity of studying a case of a possibly unfamiliar skin disease, and requested him to strip. There were numerous excoriations upon the trunk and extremities, but the wrists, abdomen, and genitals were free. The intense itching, he informed me, had developed suddenly after a night in a sleeping-car. I was quite puzzled, at first, to account for the pruritus, but, from the character of the excoriations, decided that it was a case of pediculosis. My friend scouted the idea, as he had already examined his clothing, with a negative result, but in a few days he wrote me as follows: "Your diagnosis has been confirmed. I went on another tour of inspection after I reached home, and found *six*. They were secreted in the folds of the underclothing in the very localities where the itching was most intense. I had a bright light and two pairs of glasses, and the flat, colorless cusses nearly escaped my vision even then." In a postscript, he added: "Another case of prairie itch explained!"

Chronic urticaria is also a disease in which it is not always an easy matter to arrive at a correct diagnosis, inasmuch as the wheals are ephemeral in character, and when the patient is examined by the physician there is usually nothing but excoriations to be seen. Indeed, the diagnosis in most cases of chronic urticaria cannot be based upon the eruption present at the time of examination, but must necessarily depend upon the history given by the patient or upon the peculiar irritability of the skin which permits the artificial production of wheals. When there exists in the mind of the physician a firm belief that some peculiar pruriginous eruption is epidemic in his section of country, it is not strange that both urticaria and the papular form of eczema should be associated with scabies, pediculosis, and idiopathic pruritus, and all of the doubtful cases considered to belong to a new and undescribed disease.

It is extremely questionable, in my opinion, whether any form of pruriginous eruption prevails in the West which we do not meet with along the Atlantic coast. Until clinical facts are forthcoming which will prove the contrary, I shall continue in the belief that the so-called prairie itch is a myth, and that its name is merely a euphemistic expression which has been found convenient to cover an uncertainty in diagnosis.

18 East Thirty-first Street.

OVARIOTOMY IN A PATIENT EIGHTY-TWO YEARS AND FOUR MONTHS OF AGE—RECOVERY.[1]

By JOHN HOMANS, M.D.,

BOSTON, MASS.

A LADY of the age above mentioned was referred to me through the kindness of Dr. Charles A. Dewey, of Rochester, N. Y. The patient was a widow, and had been the mother of five children, the youngest being forty-three years of age. On examination I found a tumor of the left ovary, apparently without adhesions, in an active, healthy woman. The presence of the tumor had been known for about two years, and it had grown rapidly during the last six months. The lady said that if the tumor was likely to render the remainder of her days uncomfortable, she would like to have it removed.

On January 28, 1888, I removed the cyst, which proved to be one of the left ovary, somewhat multilocular and papillomatous. The fluid weighed thirteen pounds, and the solid portions one and three-quarters pound.

On the sixth day the temperature rose to 100.5° F., but subsided the next day, and the patient went home on March 2d. The oldest women on whom I had previously operated were each seventy-three years of age—one on November 19, 1881, and the other on December 26, 1883. Both of these ladies are now living in good health. Sir Spencer Wells' oldest case was seventy-one, and Dr. Keith's seventy-three. Mr. E. Matthews Owens, of Australia, has just operated successfully on a patient seventy-nine years and ten months of age. I could find no case as old as eighty years, but, to make assurance doubly sure, I communicated with Dr. J. S. Billings, at Washington, and at his request Dr. Lorini made a thorough search without finding any case recorded older than seventy-eight years of age.

"WASHINGTON, March 16, 1888.

"DEAR DOCTOR: Some days since, Dr. J. S. Billings handed me a letter, with the request to look up the subject of ovariotomy in women of eighty years and over. Through the kindness of Dr. Robert Fletcher I have been enabled to see the cards of the unpublished catalogues, numbering several thousand. I have looked up all the statistical tables obtainable, and consulted all the works on the subject in all languages, including Russian, Swedish, Hungarian, etc.—in a word, I have been over the subject most carefully and have failed to find a single case recorded in any journal, pamphlet, or book.

I found quite a number of cases where the operation was done in women of seventy years and over; the oldest cases being two, reported in Italy, in women seventy-five years of age, and one in Russia, seventy-eight years of age. The result is a disappointing one to the seeker, but it will probably be satisfactory to the gentleman who ordered the work done. I enclose bill for services.

"Yours very truly,
(Signed) "R. LORINI."

It will be seen from the above that not a single case of ovariotomy in a woman eighty years of age, or older, has ever been reported, if Dr. Lorini's search has been exhaustive, and I think we may consider it so.

A BIOGRAPHICAL SKETCH OF THE LATE MIDDLETON GOLDSMITH, M.D., LL.D.[1]

By JOHN C. PETERS, M.D.,

NEW YORK.

DR. GOLDSMITH only lived in New York from 1837 to 1845, but during that time he became one of the founders of this Society. Most of the rest of his life was spent in Vermont. Few of our members had ever seen him, and still fewer have any clear conception of the man. Yet his life was a very picturesque one, crowded with good works, and crowned with great successes. His professional renown commenced very early, for he was a good anatomist and almost a great surgeon while yet in his teens. He commenced to dissect when some of his boyish companions were still whittling sticks. His father, Dr. Alban Goldsmith, was Professor of Surgery in the Louisville, Ky., Medical School, and Middleton had served as his prosector and clinical and surgical assistant, and performed at least one amputation of the thigh before he was eighteen years old. He always seemed to have anatomy and surgery at his fingers' ends.

In 1837, when he was nineteen years old, his father was appointed Lecturer on Surgery in the New York College of Physicians and Surgeons, then in Crosby Street, and Middleton, of course, continued to assist him. This college was then the only medical school in New York, and in 1837, when I first sat upon its benches, it had less than seventy medical students. Philadelphia then had four times as many medical colleges, and more than ten times as many matriculants. Now the disparity is not so great. Middleton graduated from the College of Physicians and Surgeons in 1840, aged twenty-two, and almost immediately sailed to India and China, as a ship's surgeon.

On his return he established, with the aid of Drs. Markoe, Sayre, La Conte, and others, the first Alumni Association of the College of Physicians and Surgeons, and contributed largely to the first volume of its Transactions.

---

[1] Believed to be the oldest case on record.

[1] Read before the New York Pathological Society, April 18, 1888.

The Goldsmiths, father and son, were great naturalists, and very fond of rare and handsome birds; hence Middleton was soon found assisting the great Audubon in the dissection and classification of some of "the Birds of America." They had many artistic and æsthetic tastes, and their beautiful rooms in Park Place were filled with handsome illustrated books, fine engravings and paintings, splendid cameos and musical instruments, besides being loaded down with brilliant surgical apparatus. There were then no stores in Park Place, or on Broadway, near by. These wide streets were filled with stylish private residences, and the great Park on the east, and the lovely Columbia College grounds on the west, made the whole neighborhood delightful.

But the Goldsmiths came, on one side, from "a race half aristocratic and half bucolic; as simple as shepherds and as proud as kings;" hence Middleton was often found at Bull's Head in search of tape-worms, hydatids, liver flukes, and other curious pests of animals. He also made many minute dissections of the eyes of men and animals for a prominent oculist, and even taught him how to operate. He was a great favorite with the genial but eccentric Dr. John W. Francis, some of whose peculiarities he may have imbibed. Dr. Francis always spoke of him as the last lineal descendant of the great Oliver, and as a poor medical orphan, who had no uncles in the New York or Bellevue Hospitals to help him on. In return Middleton poked great fun at the triplex and complex pills, and the big and little worms, gall-stones, and bilious disorders which Dr. Francis believed they cured.

He visited the dead-house in the Park every day to make autopsies for the coroner, and, when there were no other subjects, he and I cut up the bodies of the paupers, which were merely sent there for burial in Potter's Field, which used to be in Washington Square. I well remember his long and swift, but skilful, way of cutting; the quick hari-kari-like, or "happy-dispatch" way with which he went through a cadaver, without any rough mangling or jumbling of things. All was orderly and rather artistic.

At this time he was a remarkably tall man, considerably over six feet high, muscular, but not gross, and exceedingly well-proportioned. He was quick, but easy and even graceful in most of his gestures and movements. He had reddish hair, a fair complexion, a handsome and pleasant face, and was very neat and even showy in his dress. He was a reasonably good Greek and Latin scholar, but especially a perfect master of the English language, which he always spoke and wrote with great purity and conciseness. He was very fond of Burns and Shakespeare, and that grand old pagan, Hesiod, whose "Works and Days" and "Theogony; or, Creation of the World and Gods," he delighted in all the days of his life. He sometimes made verses, which he called poetry; always sang a good song, and sometimes a better psalm tune; he could play on the guitar and banjo; was a good talker, a capital story-teller, and quick at repartee. He soon became a great favorite in medical, social, and religious circles, and often shone in the best assemblages of the brightest men and nicest women. He was looked upon as a sort of modern Apollo and Admirable Crichton, and the most rising young surgeon in New York. But he blazed in his greatest glory when he paraded as Brigade Surgeon on Major General Sandford's showy militia staff. He was always gallantly mounted, for he was born in Maryland, reared in Virginia, and trained in Kentucky, and knew what a good horse was. Dr. Sayre and I often gazed at him with admiring, but also envious, eyes. How different was his composed and stately bearing from the grotesque performances of Regimental Surgeon Paine, who always appeared on "Training Day," crowned with an old revolutionary cocked hat, with a big red feather in it; armed with an ancient cutlass buckled over his every-day frock-coat; and mounted on a vicious little Vermont pony, which pranced, and kicked, and buck-jumped in such outrageous fashion that Martyn sometimes seemed seated on his horse's ears and sometimes nearer the ground.

Middleton occasionally mounted a metaphysical high horse, and used involved language, so tumid as to be scarcely intelligible, but which immensely tickled Dr. Sayre, and would have greatly pleased a High Dutch Professor of Transcendental Philosophy. He also always had a great deal of what Hughlings Jackson calls "mental diplopia," *i.e.*, he could look equally earnestly and impartially on both sides of a question, and could not only defend each view with the greatest ingenuity, but with the most perfect good faith and honesty.

In those times French pathology was in the ascendant, and the Goldsmiths and many other New York physicians were worthy disciples of Cruveilhier, Andral, Louis, Civiale, etc. I had been educated, in part, in Germany, and was filled with enthusiasm for Rokitansky and the Vienna school of pathology. Dr. Goldsmith and I often talked over pathological matters in the dead-house and elsewhere. He wished me to send to Vienna for barrelfuls of specimens, and to found a pathological society, of which none then existed in the world. Dr. Sayre also wanted to establish a pathological society, and soon I was invited to attend a preliminary meeting for this purpose at Dr. Sayre's office, and am said to have made my appearance with two pailfuls of specimens, collected by Dr. Goldsmith and myself. Middleton preferred the plan of the Boston Society for Medical Improvement, which was partly clinical and partly pathological. Dr. Sayre had a plan for a purely pathological society, and he and Dr. Goldsmith persuaded those ripe pathologists, Dr. John A. Swett, John A. Forry, Thomas M. Markoe, Gustavus A. Sabine, Robert Watts, William C. Roberts, and others to join them; and soon Willard Parker, Alonzo Clark, John T. Metcalfe, William H. Van Beuren, and others of like stamp were added to the number and quickly overshadowed the three original suggestors and founders of this society, which undoubtedly were Drs. Goldsmith, Sayre, and J. C. Peters.

The first meeting took place on June 14, 1844, and in less than six months Dr. Goldsmith was called to the Chair of Surgery in the Castleton, (Vt.) Medical College. He never returned permanently to New York, but never forgot the New York Pathological Society, which he regarded as a bantling of his own, and finally made a generous bequest to it to increase its honor and usefulness.

In Castleton Dr. Goldsmith lectured and operated for ten years, making a great reputation and gaining many friends, most of whom clung to him during the rest of his life. Dr. Sayre won a prosectorship, and fell heir to the Brigade Surgeoncy and to the magnificent uniform, which he had to let out over the chest and elsewhere; for although he was not too large for his own trousers, he was for Goldsmith's.

In 1851 Middleton was chosen President of the Vermont Medical Society, after only six years' residence in the State, and made a capital report to it on fractures.

In 1856 he was called to Louisville, Ky., to the chair of surgery which his father had filled before him, and soon became Dean of the Faculty. He was summoned occasionally to New Orleans, St. Louis, and other distant places in consultation and to operate. Sometimes he got a barrelful or less of rare old whiskey, as well as thousand dollar or smaller fees from G. P.'s, or grateful patients; but he always preferred hard cash to hard liquor. He often had to treat what Shakespeare called "the rotten diseases of the south, such as gripes, ruptures, fistulas, gravel in the back, stone in the bladder, big livers, and aching bones;" but he was specially noted for his skill in operating on the eye, and for successfully crushing stones in the bladder.

When the civil war broke out he promptly offered his services to the Union, and commenced as Brigade Surgeon in the Army of the Cumberland in 1861. Soon he was Medical Director in General Buell's army at Shiloh;

next, Inspector of Hospitals in General Grant's army at Corinth; and, finally, Surgeon-in-Chief of all the military hospitals in Kentucky and the Army of the Ohio. It is hard to overestimate the good work which he did in these honorable and important positions. In addition, he discovered the virtues of bromine in hospital gangrene and kindred diseases. He must be regarded as one of the great pioneers of disinfection, as Lister did not commence his experiments till 1866, and little was known about carbolic acid before 1870. When his sick and wounded were dying for want of warm clothing, he disinfected condemned blankets and overcoats, which had been used by small-pox patients, with bromine, and succeeded so well that he not only used these clothes himself, but permitted his whole family to do so also.

He now broke down completely under a severe and prolonged attack of camp diarrhœa, but persisted enthusiastically in working up his views on bromine. His attractive daughters had many suitors, whom he quickly pressed into the dreary task of copying papers on gangrene, pyæmia, etc. As none of them were medical men they naturally thought they had fallen on hard lines indeed.

At the close of the war he endeavored to resume his practice in Louisville, but his outspoken Union sentiments rendered him so unpopular that he was forced to return to Vermont, where he remained, in Rutland, for the last twenty-five years of his life. He did not again enter into general practice, but played a large rôle in surgery, as a consulting physician in obscure and difficult cases, and as an expert witness in medico-legal trials. He soon again became a power in Vermont. He established the Rutland Free Dispensary, and was ever ready with his purse and services. There is no part of his history which is more clear and creditable to him than his devotion to the poor. He not only treated those who came to him, but sought out many who could not easily get other medical or surgical aid; and generally also paid their board bills. He was often crusty and abrupt to the rich, and is said never to have yielded to the whims of his patients unless they were very poor, or very old, or in some way peculiarly unfortunate. On alternate Sundays he would drive far out to the marble quarries and prescribe for all the women and children of the Irish laborers. On other Sabbaths he would go to the wood-choppers' camp for the same purpose. He never exacted fees for these services unless the men were careless or brutal to their families. Then he not only charged high, but made an effective use of language. Some of the laborers would slip their silver dollars into the big pockets of his huge shooting-jacket, where they would often be found long afterward, mixed up with cartridges, prize potatoes, and packages of fish-hooks. He had as much influence with this class of people as their priests and clergymen; and was a great friend and chum of good Catholic priests, kindly Congregationalists, jolly, shouting Methodists, quaint hard-shell Baptists, and gentlemanly low church Episcopalians; but he looked askew at canters and ranters and bitter Calvinists, and had rather a disrespect for his Satanic Majesty, and for his brimstone and the place where he is said to burn it. As the New England Sabbath always ended on Sunday afternoon, he generally had a gun and fishing-rod quietly stowed away in his wagon.

He delighted in assisting young doctors by good counsel, by speaking a kind word for them where it would tell, by helping them in their operations, and by lending them medical books and surgical instruments, many of which he never got back again. Still, he always had the largest medical library in Vermont, and the greatest collection of surgical instruments, besides several big galvanic batteries and unusually fine microscopes; all of which he knew how to use.

Although very fond of his professional work, he steadily began to delight more and more in out-door pursuits and pleasures, in fine horses, cattle, sheep, dogs, guns, farming and gardening, or as the old geographies put it, in "hunting, fishing, and war." He became a sportsman and naturalist in the best sense of those terms, for there was not a plant or flower, or seed or grain, or bird or fish or animal that he did not know all about.

He always had great respect for

> That germ, but faintly understood,
> Whose growth is hid in motherhood,

and hence engaged in breeding fine horses, cattle, sheep, dogs and even fish, and helped to make Vermont a great cattle and sheep-raising State. Next he had model farms and raised choice grain, fruit, flowers, and potatoes. He even tried hard to make Vermont cider as attractive as sour Rhine wine. In short there was scarcely any branch of useful domestic knowledge with which he was not familiar. He never failed to master any subject in a comparatively short time, and whatever he studied soon yielded good practical results to some one. He required ready outflows for his surplus energy and always selected agreeable or beneficent ones. His surgical work was like second nature to him, as he had been operating largely for thirty years or more. In short he had long reached that highest and best development of his faculties when they had become, as Schiller says, almost automatic without ceasing to be either accurate or earnest. As his bucolic side predominated more and more over his aristocratic tendencies, so did he shed his conventional and professional clothes and dress more and more like a prosperous farmer and woodsman. He could not and said he would not always look like a first-class undertaker or immaculate head waiter. His broad-brimmed stiff hat, which was both sunshade and umbrella, could be seen from far off, and there was no other in Vermont like it; his boots were apt to be high and waterproof, for he never knew when he would wade for trout, or plod for partridges, and his coats were often like large shooting jackets, or a collection of game bags. On week days he often had a long bamboo fishing-pole sticking out behind his wagon, but he drove fleet horses and was rarely dusted on the road.

He was generally provided with a medicine chest and case of surgical instruments, was always ready for any emergency, and came into the sick room like a wholesome and cheery breeze of wind on a sultry day. He had no favorite operations, but was always called upon when unusual skill was required, and is credited with the usual prodigious number of big tumors, aneurisms, amputations, and of operating on all sorts of strangely visited people, the despair of other surgeons. It is even said that he would not even leave a mole, or mother's mark, or hare lip, or ugly scar to disfigure fair women, or pleasant children.

As an expert witness he was without a rival; a terror to opposing lawyers, whose cross-examinations he always turned against themselves, and is said never to have been defeated. His commanding presence was so impressive and his testimony was so clear, concise, and positive that the jury always believed that only they and he understood the case rightly, and if necessary would have over-ruled the judge and the laws; but he always obtained the approbation of Chief Justices Peck and Shaw, Judges Phelps and Barrett, Governor Stewart and other great and honest lawyers.

As a philanthropist and hygienist, he was a great thorn in the sides of ignorant or lazy health officers. He found the Vermont State Asylum crowded with over five-hundred inmates when there was only room for one-hundred and fifty. Besides, the State was only allowing $1.40 a week for board which cost nearly $3, and was not even paying that poor pittance, as it was $30,000 in arrears. We can easily imagine him saying to the Governor and Legislators: "If your excellencies will not merely put your venerated noses in these overcrowded rooms at midnight, but will endeavor to sleep the rest of the night in them, you will find out all about foul air, and what we doctors call lack of ventilation. If you will ask your thrifty wives to feed and clothe these poor patients on the scanty State allowance they will soon give you lessons in domestic economy that you will never forget, or else I have strangely underrated the generosity and justice of Vermont women."

He drew up the game laws of Vermont, which have been the models for those of several other states, making sportsmen and hunters the wise and generous protectors of game in the breeding season. Then poachers and pothunters had no rights which any decent man was bound to respect. When fish and birds and wild animals were mature, swift, cunning and strong, he could whip a stream, snare birds, and shoot beasts with the best of them; then he almost rivalled the poachers, especially when he wanted delicate food for poor patients. His game laws were of course attacked, but it is shrewedly suspected that the most astute and bitter criticisms came from his own pen anonymously, and that he greatly enjoyed his own apparent discomfiture.

Need we be surprised that when such a man died there was a great outburst of overwhelming sorrow from his neighbors, and that his distant friends were almost astounded at the tremendous praise which was heaped upon his memory. But when we find that even his mother-in-law, and his brothers-in-law, and sons-in-law, joined heartily in this praise, we must believe it well bestowed.

We can never forget him. Several years ago he gave this society a large sum of money to found a lectureship; for many months he had been endeavoring to give us his large and valuable medical library, estimated to contain 6,000 volumes. Then his dear wife, whom he did not expect to outlive, was suddenly carried away to a better world, and he was stricken down with deadly grief, helpless and unconscious from which he only aroused sufficiently to complete his generous gifts to us and to the Academy of Medicine.

Oliver Goldsmith wrote: "Innocently to amuse the imagination in this dream of life, is wisdom." Middleton Goldsmith acted as if he might have said: "To usefully and generously train our brains and our hands and our hearts in this royal game of life is still greater wisdom."

Clinical Department.

ACUTE ŒDEMA GLOTTIDIS—INTUBATION—RECOVERY.

By G. C. H. MEIER, M.D.,

NEW YORK.

The case here reported being the first one, as far as I can ascertain, of intubation in the adult for œdema of the glottis, will, I hope, be of some interest to the profession, and help to more firmly establish the practice of intubation in preference to tracheotomy in suitable cases.

G. S——, aged thirty-six, brewer. Patient enlisted my services on March 13th, for a little hoarseness, with slight dyspnœa and some pain in swallowing in the region of the larynx. He complained also of a slight bronchial cough. Temperature normal, pulse good; ordered medicated inhalations, and a mixture of muriate of ammonia.

March 14th.—Respiration easier, some hoarseness still present, no pain or cough. Feels pretty well.

March 15th.—Patient, contrary to my orders, got up and stood before the door of the restaurant where he boarded, then lay down on his bed to sleep, and in a short time was taken with severe dyspnœa. I found him laboring intensely for breath; he was enveloped in a cloud of steam from his body, and the perspiration was literally pouring down his forehead and neck. He was unable to lie down or even sit, but was continually moving about. Retraction at lower border of sternum was very marked, and auscultation revealed nearly entire absence of respiratory murmur. Inspiration was accompanied by a stridulous sound, while expiration was also audible, but not so marked. Face anxious, puffy, and cyanosed; lips bluish. A hypodermic injection of morphine and atropine was at once administered, an emetic prescribed, and hot inhalations ordered. Hot moist cloths were also bandaged around the neck. The emetic failing to act after ten minutes and the respiration not becoming freer, six leeches were applied externally over and below the larynx. In about half an hour the severe distress of breathing diminished somewhat, and the patient ceased to perspire, and was able to compose himself and to sit on the side of his bed. A powder of calomel, jalap, and rhubarb was administered. Professor Ripley was then called in consultation, as I did not wish to leave my patient for the night without further advice. Dr. Ripley concurred in the diagnosis, but did not think that the patient was then in any immediate danger; he suggested turpentine to be added to the hot water for inhalation, and a flaxseed poultice around the throat. This was continued during the night. Patient still had labored breathing when we left him; this continued till toward morning, having become somewhat worse again about midnight. Toward morning the patient got a little sleep, and when I saw him he was breathing comparatively freely. The breathing, however, was by no means noiseless. Urine was now examined and some albumen found. There was no other indication of nephritis at any time, and the albumen may have been only temporary and due to congestion of all the viscera, produced by the extreme dyspnœa.

March 16th.—At about 5 P.M. the patient had another sudden accession of dyspnœa. I did not feel at liberty to further temporize with internal medication, and asked Dr. Dillon Brown to intubate, which he very skilfully did, using a hard rubber tube and relieving the patient almost instantly. Dr. O'Dwyer very kindly came to see the patient soon after, and when he arrived the tube was *in situ* and the patient was breathing perfectly freely—indeed better than at any time during my attendance.

March 17th.—The patient passed a very good night, and when urged to go to the hospital for further treatment, did not think it necessary, as he felt all right. He was, however, prevailed on to be moved to Bellevue later on in the day.

Again, on March 19th, I saw the patient with Dr. Brown at the hospital. He wanted to go home, as he considered himself perfectly well. He coughed up the tube about an hour before we saw him, and was none the worse for its absence. He said that the tube was loose for some hours, and that he kept it in place by swallowing it down whenever he could feel it slipping up. When it was expelled, a slight cough brought it up into his mouth. A further examination of his urine will be made to determine whether the œdema was due to Bright's disease, or whether it was due simply to a localized laryngeal congestion.

A Grim Jest-book might be compiled from the prescriptions filed away in the shops of druggists, many of them reposing in austere loneliness under a disguise of execrable hand-writing. The following has been rescued from an obscure pigeon-hole by a Chicago paper, and is a relic of the pioneer doctors of fifty years ago: "A Recipe for Armilda Purdy's Lung Complaint.—Take of the bark of wild Cherry, Sassafras, Sycamore, yellow poplar, Dogwood and black oak, a Double handfull of each; take of Sasaparila Root and Spignard one handfull of each; to which add three Gallons of water. Boil it Down to one; strain it and add one quart of Good french Brandy and one quart of Honey, of which take about one Gill three times a day. This was tryed by Jonathon Douglas when he Could not Set up and has Cured Several others. N.B.—If She Canot take agreeable to Directions Take what She Can."

Progress of Medical Science.

The Clinical Significance of Albuminuria.—The following editorial comments on the subject are made by *The Lancet:* "Albuminuria may seem of late to have lost a good deal of its significance as a clinical symptom. On the one hand, it has been shown that serious degeneration of the renal organs may have occurred, and even advanced to a fatal termination, without albumen having made its appearance in the urine; on the other, we have increasing evidence to show that albumen frequently appears in the urine under conditions that differ but little, if at all, from the normal. Under these circumstances there is a danger lest the routine examination of the urine for albumen be neglected, or, even if regularly practised, the importance of its detection insufficiently appreciated, since its presence thus seems to have but slight determining influence. Already there is a tendency on the part of patients, when the verdict of albuminuria associated with renal changes has been pronounced, to appeal to others, whom they hope may be likely to prophesy smooth things; and where such opinions are sought in merely casual consultations, too favorable verdicts are likely to be given in cases where the definite character of the renal changes is not otherwise well marked—a point which Dr. George Johnson particularly emphasized in a recent communication to *The Lancet.* Thus too great assurance often results from the non-detection of albumen in cases where, from the polyuria, the tense pulse, and the heaving left ventricle, the medical attendant has been led to suspect the existence of renal disease. Mistakes in this direction, however, are now less excusable than before the researches of the late Dr. Mahomed into the pre-albuminuric stage and its association with increased arterial tension, who before his death had collected abundant evidence establishing the fact that the kidneys examined post mortem in many patients dying at Guy's Hospital, whose urine, though repeatedly examined in the wards, had never been in the slightest degree albuminous, exhibited considerable degenerative changes. Professor Dieulafoy has made similar observations, and has even gone so far as to describe the progression of the symptoms observable in the pre-albuminuric state. This important fact, which is really the outcome of the exhaustive and elaborate researches of Gull and Sutton, is not only of immense importance to the physician, who, by the early detection of the disease during the pre-albuminuric stage, is enabled to arrest, or rather control, it by hygienic and therapeutic treatment, but also to the surgeon, who would decline an operation if the warning symptoms were present, notwithstanding the absence of albumen from the urine."

At the present moment, however, the attention of urinary pathologists is directed more toward the clinical significance of albuminuria occurring in persons apparently healthy, or, perhaps, to speak more correctly, not presumably suffering from organic disease. For many years physicians have been aware that albumen intermittently makes its appearance in the urine, but, owing to the infrequency with which, in days gone by, routine examinations of the urine were made, little attention seems to have been drawn to the fact. With the advent of a stricter clinical examination of the urine, the frequency with which "intermittent albuminuria" occurred was noted, and immediately explanations were forthcoming to account for the phenomenon. Dr. Pavy, noticing the tendency to the periodic recurrence of the albuminuria, especially during the morning hours, the time when the alkaline tide is also at its highest, regarded it as connected with a physiological cyclic change occurring at that period of the twenty-four hours. Dr. Pavy's views have been criticised, and at the time he brought forward his theory we pointed out that this cyclic appearance of albumen may be anticipated or postponed by making the patient rise from bed earlier or later. Indeed, as Dr. Stirling in a recent paper in *The Lancet* remarks, the condition is probably due to a temporary state of paresis, owing to the sudden filling of the renal vessels caused by the patient rising from the horizontal position in the act of getting out of bed. The frequent occurrence of an intermittent albuminuria in young persons has led to the term "adolescent albuminuria," a term permissible only so long as we remain unacquainted with the conditions that produce it. Many explanations have been offered, but no one is completely satisfactory. It is probably due to a weakened state of the renal vasomotor centres, which are easily thrown off their balance by exaggerated physiological conditions, such as over-exercise or indigestible food; by over-stimulation of the generative apparatus—masturbation in the male, and disorders of menstruation in the female. With respect to the latter, we should bear in mind Dr. Matthews Duncan's observation of the frequent connection of albuminuria with parametritis. Over-study or anxiety also seems a frequent cause. Most hospital physicians are consulted by some of the students of their respective schools every year, with respect to the temporary appearance of albumen in their urine, especially prior to the examinations, and hear nothing more about it when these crises are over. Sir Andrew Clark, at Dublin, was able to give very interesting information on this point with regard to the effect the civil service examination has in the causation of albuminuria in urine of many of the candidates. As distinct from cyclic and adolescent albuminuria, Dr. Ralfe (*The Lancet,* October 25, 1886) has described a "paroxysmal albuminuria" very closely resembling hæmoglobinuria in many of its clinical characters, the blood-coloring matter being alone absent. In these cases an increase of urea and the presence of urobilin is usually noted, whence that observer infers that the albuminuria is caused by an increased hæmolytic action of the liver on the corpuscles. This examination of the other constituents of the urine at the same time that the presence of albumen is determined, and the comparison of them with samples passed when the urine is non-albuminous, seem to us most likely to yield definite information regarding the causation of the albuminuria in many of the anomalous forms. But the inquiry should not stop at the determination of the urea and urobilin, indican, etc., but be extended to the character of the albumen itself. As Dr. Saundby very rightly observes, if the albumen in the paroxysmal form of albuminuria is derived from the blood-corpuscles, a large proportion ought to consist of paraglobulin. With regard to the question of the existence of the two forms of albumen in the urine—paraglobulin and serum-albumen—in some forms of albuminuria, we cannot pass over Dr. Herman's interesting observations, recently communicated to the Obstetrical Society, of the condition of the urine in puerperal eclampsia, in which he confirms the statements of Maguire and Ralfe that the paraglobulin is in excess of the serum-albumen, and this he found to be especially so with cases of the congestive and *foudroyant* type. These observations are especially interesting as pointing to the conclusion that the changes in the kidneys are brought about by changes in the blood rather than, as has been generally taught, by mechanical pressure, either direct or indirect. We might extend this article almost indefinitely, but we have said enough to show that albumen has not lost its interest or importance as a clinical symptom, but that every individual case of albuminuria requires close and attentive study; above all, we would insist that too hopeful views should not be taken, certainly as far as treatment and enforcement of hygienic regulations are concerned; for we are ready to endorse Dr. Johnson's opinion, that often intermittent albuminuria is a prelude to the more persistent and fatal form, while we know that artificial induction of albuminuria in animals is, after a short time, always followed by changes in the glomeruli and tubules. On the other hand, if care and attention be paid to dietetic and hygienic considerations, the patient's life may be considerably prolonged, and the advent of the more grave form of disease postponed for many years.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, May 5, 1888.

HIGH LICENSE AND THE PROFESSION.

WE shall not be accused, we trust, of a professional bias in expressing the opinion that the high-license bill is the most important measure which our legislators have this season considered. This may be honestly stated on purely humanitarian grounds, without any partisan reference. The far-reaching effects of drunkenness bring the matter to the personal attention of every medical man.

That too much liquor is drunk by all classes in the community no one will deny. Its effects are transmitted from one generation to another. Very few authorities now believe that the distinct craving for alcohol is transmitted from father to child, but all recognize the peculiarly unfavorable environment of the child of a drinking father. This latter circumstance is made much of by philanthropists, who excuse what a moralist would condemn. It is made much of by intemperate men who, excuse their own shortcomings by the statement that their grandfathers drank.

The religious element of the community is apt to consider drunkenness in a different light. With them it is not a disease or inherited tendency. It is a positive sin, which they place in the same category (quoting Scripture) with "adultery, hatred, murders, and such like." Admitting the truth of this view, it is yet evident that measures are called for that shall remove temptation from those liable to fall, and this we believe can be best done in the present state of public opinion by the operation of a high-license statute.

The medical view of the matter is a middle one between the two above stated. Many of the diseases from which mankind and womankind suffer come from direct violation of physical laws, though they may not be so terrible in their application as is alcoholic excess. They do not so directly lead to crime and others' misery. We are hardly prepared to go so far as do some who have made the subject of inebriety a special study. The conclusions which they state seem altogether too radical as a basis for practical procedure. We think that the doctrine that the inebriety of any person is in itself evidence of more or less mental unsoundness is a dangerous one to admit without qualification.

But, in any event, it is evident that the present sale of liquor must be greatly restricted, and, as we have said, high license seems more likely to bring about this result than any other plan. As moral sentiment advances, the law can approximate in stringency to absolute prohibition. The tendency is to make the question one of party politics. A political side it certainly has, for advance can be made only through political agencies, but it has also a social aspect which we, as guardians of the public health, are bound to consider. It has never been the practice of our profession to assume sides with any party, and it need not do so now. Still less need it act through any of its own societies or associations. But, as a citizen, each one can bring his personal influence to bear in favor of high license, and help to relieve modern society of its greatest curse.

THE LOMB PRIZE ESSAYS.

IT is well known that Mr. Henry Lomb, of Rochester, has offered in time past, through the American Public Health Association, cash prizes for the best essays on sanitary topics. This offer has led to the publication of some very noteworthy monographs on the assigned subjects. This year the offer is repeated. There are to be two prizes, the first for five hundred dollars, and the second for two hundred. The topic selected is in every way a most admirable one, viz., "Practical Sanitary and Economic Cooking, adapted to Persons of Moderate and Small Means." Pursuing the prospectus still further, we find that the essays are to cover, in the broadest and most specific manner, methods of cooking as well as carefully prepared receipts for three classes: (1) Those of moderate means; (2) those of small means; (3) those who may be called poor. For each of these classes receipts for three meals a day, for several days in succession, should be given, each meal to meet the requirements of the body, and to vary as much as possible from day to day. Formulas for at least twelve dinners, to be carried to the place of work and mostly eaten cold, should be given. The combined considerations should be healthfulness, practical arrangement, low cost, and palatableness.

We are glad to note the extremely practical character of the topic. Its application to the daily life of our poorer classes may still be a long way off, but a beginning must be made at some time and in some way. The cost of food is not at the present time exorbitant. The price of any article may be raised occasionally by the manipulations of "trusts," but the rise is only temporary. Competition among the circles of food-producers is so keen that prices are, on the whole, low. But it is very evident to anyone who sees much of the poor that the great trouble lies, in the main, not in their inability to procure proper amounts of food, but in their ignorance as to how to utilize what they already have. We use the word "utilize" in the sense of making nutritious and palatable.

Many will doubtless recollect the series of letters on "Prisoners of Poverty" which were published in the Sunday *Tribune*, awhile ago, by Mrs. Helen F. Campbell. These communications were based on personal observation of the poor in their homes, and brought out with painful clearness the fact that the great mass of the tenement-house population have a very faint idea as to how properly to prepare the plainest and cheapest kinds of food. Tea is the universal drink, and frying the general mode of cooking.

There is no field of philanthropy calling more loudly for help than this. All physicians who see any dispensary practice know how completely the effect of treatment is nullified among the poor by dietetic vices. These latter arise, we again affirm, not so much from the lack and poor quality of food as from improper modes of preparation. The admirable lectures of Miss Juliet Corson and others before the various cooking schools have shown how much may be done in this direction. When the reform has set in and gathered some headway, we may be able to see some results from the treatment of dyspepsia and chronic rheumatism even in dispensary patients. We make the matter of diet of cardinal importance in the treatment of those maladies among the well-to-do; why not attach to it an equal importance with those who live under greater unfavorable sanitary conditions?

The public and formal discussion of the subject in the prize essays will ably supplement what has already been done, and we commend the choice of those who have selected this topic.

EMPEROR FREDERICK'S CONDITION.

It is quite difficult to reconcile the conflicting reports concerning the present condition of the Emperor of Germany. The official bulletins are purposely evasive, and it is only by a careful study of the salient points in the case that any reasonable conjecture can be offered. Strange as it may seem in view of the multitude of counsellors, no positive and satisfactory diagnosis of the disease has been made. The medical staff has disagreed to such an extent that the issue appears to be more a political than a scientific one. There never was a case of supposed cancer which has been hemmed in by so many difficulties. The German specialists are firm in their convictions as to the existence of malignant disease, while Dr. Mackenzie and his immediate associates are prudently non-committal. The latter thus far appear to have the better side of the argument against carcinoma, for it must be recollected that as yet the microscope has failed to settle the dispute. The clinical history, also, is not a classical one of ordinary cancer of the larynx. Cancer, as a rule, is not attended with sloughing, nor with persistent and acute inflammatory processes. The latter are usually explained by other specific conditions, amenable not only to local but constitutional treatment. The persistence of the local lesions can be explained only on two suppositions: Either the disease is an unusual form of cancer progressing to its end, or it is a non-malignant disease, curable under ordinary circumstances, but which has left behind it the results of sloughing—irregular cicatricial constrictions and other local changes, which are equally ominous in their ultimate results. Certain it is that the tracheotomy tube is still worn and, in itself, is causing much irritation and suppuration. In either event the outlook is a very bad one. The worst symptom is the continuance of fever, indicating the probable existence of blood-poisoning, either directly from the suppurative processes in and around the site of the tracheotomy tube, or indirectly through infection of the lung-tissue by downward leakage of the poisonous discharges through the trachea and bronchial tubes.

DOCTORS AS STORY-TELLERS.

Dr. W. P. Northrup, of this city, the worthy President of the New York Pathological Society, can see as much through a sea-glass as through a microscopic lens. In the current issue of *Scribner* he describes a cruise on a pilot-boat, which must be read with interest by everyone. The sketch is a model of its kind, and proves him to be a wide-awake observer and an entertaining story-teller. His descriptions of the rough and ready sea-life of the hardy pilot are specimens of high art in composition, and justly entitle him to the warm congratulations of his many friends. But even better than reading it is to hear him tell it. Try it again, doctor.

PETERS AND GOLDSMITH.

The sketch of Middleton Goldsmith in our present issue is one which will be read with pleasure. It was eminently fitting in Dr. John C. Peters, his old friend, to read, on the occasion of delivery of the Goldsmith Lecture for this year, an account of its founder. We envy Dr. Peters not only the pleasure of knowing such a man, but the ability to draw such lovely and telling word-pictures of the good old man. Dr. Peters is eminently felicitous in life-sketches, and we should all be willing that he should outlive us, and have his heart as warm and his head as clear as they are now. We never knew Goldsmith, because he was before our time, but we have learned to love and admire him after reading the sketch. It is a clear and bright life-view, with the sunset crowning the mountain.

News of the Week.

American Medical Association.—The next annual session will be held in Cincinnati, commencing Tuesday next. A full report will be published in our next issue, which will be necessarily delayed.

Yellow Fever Inoculations.—Dr. Domingo Freire's yellow fever inoculations were reported, by the French expert sent to investigate them, to be worthless. Now Dr. Sternberg, the United States Commissioner, returns and reports: "The question of etiology of yellow fever still remains unsettled; the claims of Freire, of Brazil, and Carmona, of Mexico, with regard to the discovery of the yellow fever germ are without foundation; their statements and statistics of protective inoculation for this disease have no scientific value." Says the *Boston Medical and Surgical Journal*: "The technique of both Freire and Carmona was found to be very defective, both microscopical and bacteriological, proper staining and cultures not having been performed, nor were proper precautions taken to protect the specimens of blood, etc., from contamination with ordinary bacterial forms. In fact, the organism that Freire considers pathogenic and specific, Sternberg declares to be an ordinary form, probably staphylococcus albus. The organism found by Lacerda, confirmed by Babes, was a diplococcus Sternberg found in the kidneys and other organs in two out of nine cases, or in just about the proportion that the former observer had reported; as this organism is not constant, and was absent in some cases exhibiting otherwise well-marked characteristics of yellow fever, its causative action cannot as yet be accepted. Dr. Sternberg found, in one instance, a peculiar short bacillus in the glomeruli of the kidney, but as he had not succeeded in meeting with it again, he hesitated before assigning to it any special rôle in causing the disease. The statistics of yellow fever inoculation, upon examination, were also found not to bear criticism, and, in fact, were generally discredited by the other physicians, members of the Academy of Medicine in Rio."

The Iowa Medical Law.—Attempts are being made by irregulars and quacks to amend and destroy the efficacy of the State Medical Law.—*Iowa Medical Reporter.*

The Latest Reports of Pasteur's Antirabic Inoculations.—In 1887 there were 306 persons living in the Department of the Seine who presented themselves for treatment at the Institute. Among them only two died. Among 44 persons bitten by mad dogs, and not treated by inoculation, 7 died.

"Mistura contra Neurastheniam."—An up-town druggist of this city writes that he frequently has received prescriptions written: "℞. Mist. contra neurasth. O j. Sig.— ℥ ss., dose." He asked the doctor what it was, but the gentleman in question did not know, and referred him to another druggist. Perhaps some of our readers know what the mixture is.

The Late Dr. Agnew's Will.—Dr. Agnew leaves all of his property to his wife. His will contains the following clause: "I wish particularly to express my regard for my associate, David Webster, a physician residing in New York, and for that purpose I request my executrixes and executor to give him, after my decease, such token of my regard for him as may to them seem proper."

Professor John C. Dalton.—We learn with pleasure that Dr. Dalton has nearly recovered from his recent attack of illness.

New Dispensary in Washington.—A new dispensary, called the Eastern Dispensary, has recently been opened in Washington, D. C., for the treatment of the poor of the eastern sections of the city.

The American Surgical Association has issued the preliminary programme of its meeting in Washington next September. The list of papers is as follows: Excision in Articular Disease, by Dr. John Ashhurst, Jr., of Philadelphia, Professor of Clinical Surgery in the University of Pennsylvania; Micro-organisms: Their Relation to Surgical Disease, by Dr. Nicholas Senn, of Milwaukee; Cerebral Localization: The Relation to Operative Surgery, by Dr. Stephen Smith, of New York; Case of Intercranial Tumor Removed (patient to be presented), by Dr. W. W. Keen; Experimental Researches on Gastric Fistula, and the Bearing on Gastrostomy, by Dr. J. Collins Warren, of Boston; Forty Years of Chloroform and Ether, by Dr. D. W. Yandell; The Surgical Management of Typhlitis and Perityphlitis, by Dr. W. T. Bull; The Choice of Operation for Vesical Calculus, by Dr. Hunter McGuire, of Richmond, Va.; Hernia: Its Treatment, etc., by Dr. C. H. Mastin, of Mobile, Ala.; The Radical Cure of Hernia, by Dr. George W. Gay; Certain Indications for Trephining, and their Comparative Value, by Dr. J. W. White, of Philadelphia; Nerve Stretching, by Dr. N. P. Dandridge; Nephrectomy for Gunshot Wound of the Kidney, by Dr. DeForest Willard.

The Louisville Training-school for Nurses.—Under date of April 20, 1888, we are informed that the Louisville Training-school for Nurses has just graduated its first class, and that the school is prepared to furnish good nurses for Kentucky or other doctors.

An Appropriation for the College of Physicians and Surgeons at Baltimore.—A bill has passed the House of Delegates of Maryland appropriating $10,000 for the use of the College of Physicians and Surgeons of that city, to be used in the erection of a building adjoining the City Hospital on Calvert Street. The bill provides that the College shall support one free bed for each County in the State.—*Maryland Medical Journal.*

Dr. Charles McBurney has been appointed Visiting Surgeon to Roosevelt Hospital in place of Dr. Sands, who has resigned. Dr. Frank Hartley and Dr. Richard J. Hall are appointed his assistants.

Bellevue Hospital.—Dr. R. J. Hall has been appointed Attending Surgeon in place of Dr. McBurney, resigned. Dr. George L. Peabody has been appointed Attending Physician in place of Dr. Bull, resigned.

International Congress of Anthropology.—An International Congress of Anthropology will be held under the auspices of the New York Academy of Anthropology, at Columbia College, New York City, June 4, 5, 6 and 7, 1888. Sessions from 10 to 12 A.M., and from 2 to 5. P.M.

Wasted Sunbeams.—Dr. Gouverneur M. Smith's article upon this subject in a recent issue of The Medical Record has justly excited much approving comment. The *Evening Post* suggests that some one will have to set the fashion. But, meanwhile, it commends Dr. Smith's account of skyward summer-resorts for each house as rational and pleasing, while his picture of what might be done for the tenement-house population surely is almost pathetic.

The American Association of Obstetricians and Gynecologists is the name of a new organization which seems to be a rival of the American Gynecological Society. It was organized in Buffalo, on April 19th. It will send a delegation to the Congress at Washington, this fall. The officers are as follows: President, W. H. Taylor, M.D., of Cincinnati; Vice-Presidents, Drs. E. E. Montgomery, of Philadelphia, and J. H. Carstens, of Detroit; Secretary, W. W. Potter, M.D., of Buffalo; Treasurer, X. O. Werder, M.D., of Pittsburg; Executive Council, Drs. Thomas Opie, of Baltimore; J. H. Etheridge, of Chicago; C. Cushing, of San Francisco; Melancthon Storrs, of Hartford, and Byron Stanton, of Cincinnati; Delegate to the Congress of Physicians and Surgeons, James P. Boyd, M.D., of Albany.

The Supreme Court of Texas has decided that a doctor is entitled to extra fee for testifying as an expert when summoned by the court to do so.

Mr. Thomas Bryant has retired from his post of Surgeon to Guy's Hospital. He had held this position for thirty-one years.

Proposed Law with Regard to the Embalming of Dead Bodies.—A bill has been introduced into our State Legislature which provides that "it shall not be lawful for any person or persons to introduce into or upon any dead body of any person or human being, any poisonous substance, organic or inorganic, for the preservation of the same, or any so-called embalming fluids or materials of any kind, which will, in any manner whatsoever, interfere with chemical tests which may subsequently be applied or made use of by chemists in medico-legal investigations."

Why the Crown Prince of Germany has One Arm Shorter than the Other.—An esteemed correspondent, who is personally acquainted with the Crown Prince, sends us the following interesting item: "In your issue of March 24th you reprint the statements of the London correspondent of the *New York Times* regarding the health of the Hohenzollern family. According to this writer, scrofula is perfectly at home among the members of this family, who, up to the beginning of the present Emperor's throat-trouble, were conspicuously known for their extraordinary health and vitality. It would take too much time to follow up all of the assertions made in the article referred to, but one of them, regarding the present Crown Prince, Wilhelm, I would particularly point out as entirely wrong. The *Times*' correspondent writes: 'In the Hohenzollern case not only is the Emperor suffering from this hereditary taint, but his son William is hereditarily deaf, and was born with a mere shapeless ball of flesh where the right hand ought to be.' The real facts regarding the physical condition of this prince are as follows: Wilhelm's mental faculties are conspicuously bright. He attended the gymnasium at Cassel for years, and graduated in the middle of his class. Had he been deaf at all, he could never have been educated in that way. The 'mere shapeless ball of flesh where the right hand ought to be,' only exists in the imagination of the *Times*' man, for in reality the prince has a perfect hand, but a shortened humerus. When his birth was anticipated, the good Queen of England sent two London physicians to attend to her daughter in confinement. When the time arrived these gentlemen found it necessary to make version. Their attempts at this operation, however, were unsuccessful. Professor Martin (the older) was then called, but refused to come, stating that, as he had not been considered competent enough to attend to the Crown Princess at the start, he preferred to not consult with the imported physicians. It required a direct command of the King to compel Martin to see the case. He at last went, made version, delivered the princess of a living boy, handed the child to the other attendants, and left the room as he had come, without ever taking notice of the other doctors. Some three or four days later the London physicians found the child's arm broken just below the shoulder. Whether the unsuccessful attempts of the English practitioners or the successful one of Martin had resulted in the fracture, could not be ascertained; but the prince, at least, is of the opinion that he would have been better off if his grandmother and her doctors had not interfered with him."

The Late Dr. E. G. Loring left $30,000 to his widow, his sole surviving heir.

The Preliminary Programme of the American Association of Genito-urinary Surgeons, which meets at Washington, September 18, 19, and 20, 1888, has been sent us by the secretary, Dr. R. W. Taylor. It embraces thirty-two papers, covering a large range of subjects and including nearly all the well-known genito-urinary surgeons of the country. If other associations secure as full and as representative a number of papers, the Congress will prove a brilliant success. The following is the list of papers:

1. Clinical Observations on Diseases of the Testicle. By Dr. L. B. Bangs, of New York City, N. Y. 2. Clinical Observations on Chronic Gonorrhœa; and, 3, Two Cases of Cancer of the Seminal Vesicles, with Pathological Specimens. By Dr. J. P. Bryson, of St. Louis, Mo. 4. Operative Treatment of Hypertrophy of the Prostate; and, 5, Case of Bowel ending in the Urethra of a Child Four Weeks Old—Relief by Operation. By Dr. A. T. Cabot, of Boston, Mass. 6. On the Effects of Rapid Changes of Altitude in an Advanced Case of Interstitial Nephritis. By Dr. George Chismore, of San Francisco, Cal. 7. Connection between Masturbation and Stricture. By Dr. S. W. Gross, of Philadelphia, Pa. 8. Operations on the Kidney. By Dr. W. H. Hingston, of Montreal, Canada. 9. Syphiloma of the Vulva. By Dr. J. N. Hyde, of Chicago, Ill. 10. The Curability of Urethral Stricture by Electricity: an Investigation; and, 11, The Comparative Value of Suprapubic and Perineal Drainage in Curable and Incurable Bladder Disease. By Dr. E. L. Keyes, of New York City, N. Y. 12. The Filaria Sanguinis Hominis in the United States, especially in its Relationship to Chylocele of the Tunica Vaginalis Testis. By Dr. W. M. Mastin, of Mobile, Ala. 13. A Case of Perineal Section for Traumatic Retention—Unusual Condition of the Bladder. By Dr. J. E. Michael, of Baltimore, Md. 14. The Prophylaxis of Syphilis. By Dr. P. A. Morrow, of New York City, N. Y. 15. Unusual Case of Urethral Calculus. By Dr. H. G. Mudd, of St. Louis, Mo. 16. On the Radical Cure of Stricture by Dilating Urethrotomy; and, 17, Demonstration of a Perfected Evacuator, and an Improvement in the Method of Removal of Débris from the Bladder. By Dr. F. N. Otis, of New York City, N. Y. 18. Pyæmia as a Direct Sequel of Gonorrhœa. By Dr. R. Park, of Buffalo, N. Y. 19. Retrojections in Gonorrhœa. By Dr. E. R. Palmer, of Louisville, Ky. 20. Prostatotomy for Enlarged Prostate at the Age of Forty-two. By Dr. Abner Post, of Boston, Mass. 21. A Case of Removal of both Testicles for Recurrent Carcinoma; and, 22, A Case of Nephro-lithiasis, complicated with Hydro-nephrosis, in which Lumbar Nephrotomy was Performed. By Dr. F. W. Rockwell, of Brooklyn, N. Y. 23. Some Points on the Differential Diagnosis of Bladder and Kidney Affections, with Demonstrations of the Cystoscope and other Instruments; and, 24, On the Physiology of the Bladder. By Dr. Alexander W. Stein, of New York City, N. Y. 25. Local Treatment of Chronic Urethral Discharges. By Dr. F. R. Sturgis, of New York City, N. Y. 26. Some Points on the Etiology of Stricture of the Urethra. By Dr. R. W. Taylor, of New York City, N. Y. 27. Operative Treatment of Hypertrophy of the Prostate. 28. Spontaneous Fracture of Stone in the Bladder. By Dr. F. S. Watson, of Boston, Mass. 29. The Relation of the Prostate to Chronic Urethral Discharges, and The Value of the Tolerance of the Iodides as a Diagnostic of Syphilis; and, 30, Urethral Stricture and Enlarged Prostate in their Relation to Vesical Calculus and Calculus Pyelitis, with Cases. By Dr. J. William White, of Philadelphia, Pa.—By Invited Guests. 31. The Prognosis of Stricture, based on Thirty Years' Death-record of Stricture at the London Hospital and the Practice at St. Peter's Hospital. By Dr. E. Hurry Fenwick, of London, England. 32. The Congenital Anomalies of the External Urethral Orifice. By Dr. C. Kaufmann, Zurich, Switzerland. R. W. Taylor,

Secretary.

Society Reports.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Ninetieth Annual Convention, held at the Hall of the Faculty, Baltimore, Md., April 24, 25, *and* 26, 1888.

Dr. I. F. Atkinson, President, in the Chair.

Drs. G. L. Taneyhill and Robert T. Wilson, Secretaries.

Tuesday, April 24th—First Day.

THE PRESIDENT'S ADDRESS.

He began by speaking of the evil effects of indiscriminate alms-giving and poor relief, and its tendency to pauperize the recipients. Much of such charity does a small fraction of good, but intensifies the very evils it is intended to arrest. Fortunately, there are many with wealth, kindliness of heart, clearness of brain, and energy of hand who realize that the bestowal of alms is not always true charity, that assistance to the unworthy may prove unjust to the deserving and meretricious to the recipient. A large class also does good by distributing the bounty of others. The outcome of all such united efforts at systematic charity resulted in the formation in several cities of

CHARITY ORGANIZATION SOCIETIES.

They have done incalculable good to the deserving poor. It may be profitable to consider the administration of medical charity, a subject worthy of attention and not trite. Generally, those who stand most in need of assistance are those whose misfortunes are the more or less immediate results of their own actions. Two classes receive charitable relief: 1, Those who from disease, age, or infirmity are made to work for a livelihood; and 2, those, who, suffering from neither of these disabling causes mentioned, live in idleness. All in the first class need help, and not all in the second class should be excluded. Able-bodied paupers exist since the days of strikes. The well and healthy laborer may find as a result of his toil enough compensation to supply his daily wants, but when sickness appears he appeals to charity for support. In 1872, London, with four million inhabitants, treated gratuitously at the various hospitals and dispensaries about 1,100,000 sick; 58,382 as in-patients and 1,083,674 as out-patients, and in that year £994,388 was contributed to this object; that is, about three persons in every ten in London received medical charity in 1872. The stress of work on the medical attendants in these dispensaries is so great that in one hospital (St. Bartholomew's) dispensary 120 patients were seen and dismissed one day in 70 minutes; that is, 35 seconds for each patient.

Pauperism often begins in this way. Patients able to pay are daily seen in our dispensaries and hospitals. The competition of medical schools for clinical material, and the desire of medical men for clinical experience, encourage pauperism. Persons receive medical charity who would scorn it if charity offered in other ways. The "Provident Dispensary Plan" started by Smith, of Southam, England, in 1837, has not been the success it should be. In 1874 there were only eleven such dispensaries in London. The Baltimore & Ohio Railroad Relief Association is a good example of an excellent organization for medical relief. In all such institutions membership must be compulsory. The American laborer and poor man is less willing to go to hospital than is his fellow-laborer in England. Our hospital arrangements are defective and their equipment and management inadequate. In New York City there are 3,502 public free beds and 1,418 private beds; while in Baltimore there are only 868 free beds, of which 365 are in the almshouse. Organized charity would soon weed out the undeserving cases, and the saving would more than compensate for the expense of investigation by paid officers of this society. "District Nursing" would largely increase the amount of good which the medical man does. Even the Johns Hopkins Hospital, with 120 free beds, cannot fulfil all the requirements of this community. We should work toward the perfection of our medical charities and strive for improvement in the future. At the conclusion a vote of thanks for the address was adopted.

SECTION IN SURGERY.

Dr. Christopher Johnston, Sr., Chairman.

The Chairman made the following report on the subject of

TETANUS AND ERYSIPELAS.

Surgeons boldly invade all great cavities of the body for the cure and for diagnosis of diseases. Surgery has been of great assistance to gynecology. Pathology, diagnosis, and the means of relief march hand in hand. In brain surgery, physiology and pathology work together. There exist traumatic tetanus and traumatic erysipelas, and also idiopathic tetanus and erysipelas. These diseases cannot originate *de novo*. Cold, damp, and bodily fatigue were supposed to be the great causes, but the microbe, although not recognized by some, is undoubtedly the cause in all cases. The two sides of this question are argued by the Dualists and Unicists, each having their followers. Verneuil is a Unicist; Nicolaier and Flügge believe strongly in the bacteriological origin of the disease in every form. Certain localities and soils seem to possess the power of causing tetanus. There is a tetanic district near Baltimore, and one in Long Island. Many investigators have looked for the bacillus of tetanus, with varying results. The inoculations were not always free from objection. Human tetanus is an infective disease, transmissible from man to rabbit. Many veterinary surgeons have had a succession of cases of tetanus after castration, evidently due to infected instruments. Verneuil thinks that operators may convey tetanus to man or animal with infected instruments, even if used after long intervals. Horses seem to have much to do with conveying tetanus to man. Brieger eliminated several different *toxics* from cultivation of tetanus bacillus.

The microbe of erysipelas has been isolated, cultivated, and inoculated. It seems necessary in operations to isolate patients as an element to success. The evidences of the contagiousness of erysipelas are now admitted to be abundant and satisfactory.

To summarize: The microbe of tetanus is a possibility, as also its contagiousness. The equine origin of the disease cannot be accepted. Erysipelas is propagated by a special microbe, that of Fehleisen. It has been isolated, cultivated, and inoculated. Suppurative symptoms are probably produced by the streptococcus aureus.

As a supplementary report, Dr. Robert W. Johnson read a paper on

TREATMENT OF THE SAC IN INGUINAL HERNIA.

After dwelling on the dangers of hernia and the importance of the subject, as characterized by the attention paid to it by the British Medical Association in the past year, he freely reviewed some of the early writers on this subject, and its treatment, the manner of operation, and the numerous peculiar remedies employed in different parts of the world during the different ages. He dwelt on the manner in which a patient was castrated when operated on for hernia. Banks was of the opinion that no person who could comfortably wear a truss should be subjected to an operation. There are three classes of cases: Those perfectly under the easy control of the truss, those not so, and those cases about whose contents there is any doubt or uncertainty. In all cases an operation may be justifiable, even if the hernia be non-strangulated. It may, and often does, happen that a truss is broken and the patient suffers untold agony because unable to procure another, as in the case of a sailor at sea. The sac should be removed and the wound closed with catgut sutures, as silver sutures cut the tissues.

DISCUSSION.

Dr. J. Edwin Michael spoke of the importance of making an operation for strangulated hernia radical, also for operating in cases not strangulated. There is undoubtedly some danger in the operation, but the patient is so much discomforted that with precaution an operation may be justifiable. Patient should be instructed before the operation. He explained his idea of the mechanical action of a silver suture, and thought it did not cut the tissue.

Dr. J. W. Chambers said it was no longer a question what should be done with the sac. There was little danger. He had done recently three cases with no deaths, and very little rise of temperature. He prefers catgut to silver wire.

Wednesday, April 25th—Second Day.

THE ANNUAL ORATION

was delivered by **Dr. Richard Gundry**, Superintendent of the Maryland Hospital for the Insane. He announced as his subject

SOME PROBLEMS IN MENTAL ACTION.

In a scholarly and chaste address he traced the various causes of insanity. There are three causes to which it is referable: Inheritance, environment, and personality. Each of these influences was considered at some length. As methods of prophylaxis and treatment, Dr. Gundry urged the importance of manual training as a means of mental diversion and training. Those predisposed to insanity, he asserted, should early be taught the lesson of self-control. The inhibitory power of physical exercise may be seen in various ways. "A noisy, blasphemous boy was quiet all the week, while at work, but noisy on Sunday. When set to work on Sunday he became quiet." The inebriate, the vicious, can all be reclaimed by methods of substitution, provided they themselves seize the idea and do not let it slip away. Character may be largely formed by circumstances, but our own desires have much to do with shaping these circumstances.

SECTION ON PRACTICE OF MEDICINE.

Dr. P. C. Williams, Chairman.

Dr. Williams made the following report:

He called the attention of the Faculty to several important points:

1. We should recognize the meeting of the International Medical Congress, held at Washington last year, as an era in the medical history of the world and of our country.

2. Several clinical points are of great interest:

a. The peculiar epidemic of measles in Baltimore this year. It was wide-spread, and patients had unusual nervous symptoms and unusually high temperature at a late period of the disease, with no inflammatory trouble in the lungs, and with few cases of secondary pneumonia. Extensive mortality and gradual increase of cases of measles in this city during the past winter. From October to March, included, there were 149 deaths from measles, beginning with 3 in October and ending with 49 in March—a serious showing for a disease usually considered trivial.

b. Prevalence and mortality of pneumonia in Baltimore: From October to March, included, there were 485 deaths from pneumonia in Baltimore, beginning with 33 in October and ending with 133 in March. There were many cases among the young. Before forty-five, simple pneumonia is not usually considered dangerous. The question is whether it is an inflammatory or contagious disease.

c. There has been a great prevalence of serous diarrhœa, apparently due to climatic changes, and not to bad water.

d. Fifteen years ago he had read a paper before the Society on the use of the yellow jasmine in supraorbital neuralgia. He believes it is almost a specific, and next to ergot good in cerebral congestion. The tincture is used, and a stronger tincture than usual. He stops it when ptosis appears.

Dr. George J. Preston then made a supplementary report on the subject of

PERICÆCAL INFLAMMATION.

After speaking of the ease of opening the peritoneal cavity without danger, he said that the terms paratyphlitis, perityphlitis, and appendicitis were cumbersome terms, and probably not correct, as it was doubtful if one occurred alone in man. The best division is into: 1, Typhlitis stercoralis; 2, perityphlitis; 3, appendicitis.

After reviewing the anatomy, he said that appendicitis was not easily recognized during life. He enumerated the number of objects found in the cæcum. The symptomatology is quite distinct. It is not easy to speak of its duration. Occasionally the sac ruptured, and again it sometimes takes on a chronic form. After speaking of the etiology, he said that cases of perityphlitis and typhoid fever were not seldom confused. The prognosis of simple perityphlitis is good if all obstruction be removed. Sulphate of magnesia is dangerous with inflammation. An operation should be avoided, but pus should be evacuated, and the evacuating needle as an aid to diagnosis is not so dangerous as was supposed. He cited two cases from his own practice, in one of which an operation was performed with good result.

DISCUSSION.

Dr. William B. Canfield, in referring to Dr. Williams' remarks, spoke of the part which intemperance played in the large mortality from pneumonia among the younger adults, and also of the contagious element of the disease, as well as its inflammatory nature.

Dr. Joseph T. Smith spoke of bad and unfiltered water as causing diarrhœa.

Dr. P. C. Williams replied that intemperance increased the mortality of all diseases. About seventy per cent. in hospital die of diseases in which intemperance played an important part. In the first quarter of 1887, there were 199 deaths from pneumonia in Baltimore, and in the first quarter of 1888, 335 deaths. He believed in the inflammatory theory.

Dr. William Rickert approved of recognizing the International Medical Congress. He thought that climate had much to do with the causation of measles, pneumonia, diarrhœa, and dysentery. He thought that supraorbital neuralgia was a symptom and not a disease.

Dr. Richard Gundry recalled treatment by bleeding. He thinks little of treatment, but prefers small doses frequently repeated. He fully believes that diarrhœa and dysentery are due to climatic change.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Dr. L. E. Neal read a paper comparing

CÆSAREAN SECTION AND CRANIOTOMY ON THE LIVING CHILD.

After reciting two cases he proceeded to mention the best possible treatment of contracted pelvis, by: 1, Removal of the uterine appendages before conception; 2, induction of premature labor at a period of extra-uterine fœtal viability.

After speaking of delivery by version, forceps, and other means in contracted pelvis, he said the last resort was Cæsarean section or craniotomy. Craniotomy destroys one-half of the human lives at stake, while Sanger's operation, as now performed, saves almost all mothers and children. He does not believe that pelvimetry on the living subject at term is always sufficiently accurate to be a guide, for we have no means of measuring the head of the unborn child. It does not seem as if—the natural passages being two and one-half inches conjugate—the line of natural delivery should be drawn there. Craniotomy does not seem right when death is certain for the child, while Cæsarean section gives them both a chance, and it had no effect on the mortality of the child.

DISCUSSION.

Dr. J. H. Branham thought that too little was said about the mortality of the child. The operation should be done at the time of election, and this is not at full term.

Dr. George W. Miltenberger replied that a week or two before full term was an equally favorable time. The uterus was just as fully capable of contracting then as later.

Dr. J. H. Branham thought that a week or two earlier made a great difference in the viability of the child; he also thought that we could judge of the arrival of full term by the cervix.

Dr. George W. Miltenberger did not agree with Dr. Branham at all. In a large proportion of primiparæ children are delivered one or two weeks before the time, with no harm to mother or child. It was not possible to make such hair-splitting distinctions in the condition of the cervix.

Dr. Wilmer Brinton thought that more stress should have been laid on pelvimetry, and the result will decide as to craniotomy or Cæsarean section. He did not think that foreign statistics of operations could apply to this country.

Dr. L. E. Neal, in conclusion, said that he operated as near term as it was possible to find. He does practise pelvimetry, but it does not always seem such a safe guide and free from difficulties.

SECTION ON SANITARY SCIENCE.

Dr. George H. Rohé, Chairman.

Thursday, April 26th—Third Day.

The Chairman read a paper on

THE RESTRICTION OF CONTAGIOUS AND INFECTIOUS DISEASES.

Forty-three and two-tenths per cent. of the deaths in Baltimore during the past five years were due to infectious diseases, in which are included pneumonia, consumption, and diarrhœa. Many of these diseases may be prevented by sanitary measures. Diseases are imported and domestic. There are many defects in quarantine in Baltimore. There are three ways of preventing disease: 1, By compulsory notification of contagious diseases; 2, by isolation; 3, by prompt disinfection.

1. The physician should report such diseases and should be paid for it by the government.
2. Isolation is very important, whether in hospital or in private houses.
3. Disinfection may be effectually carried out by mercuric chloride (1–500), chloride of lime, six ounces to one gallon of water, and a solution of sodium hypochlorate. Soluble phenyl is also excellent.

As a supplementary report,

Dr. John Morris read a paper on

UNSANITARY AGENTS IN COMMON USE.

This included trees, ice-boxes, refrigerators, and filters. He pointed out the dangers of too many trees about a country house, and enumerated the healthy and dangerous trees and their soils. He spoke of the danger of preserving foods, etc., in ice-boxes, and the advantages of using refrigerators through which there passed a current of cool dry air laden with the vapor of chloride of sodium and permanganate of potash. He referred to impure drinking-water and to the fallacies in many filters.

DISCUSSION.

Dr. John S. Conrad, in referring to Dr. Rohé's paper, thought that quarantine should be under the control of the government as a part of the United States Marine Service. Different degrees of strictness at different ports did harm to commerce. Crowding in quarantine sometimes spreads disease. He felt doubtful about the decided germ-destroying power of all the remedies mentioned by Dr. Rohé.

Dr. John Morris referred to three recent cases of small-pox, and the efficiency of the City Board of Health in preventing the spread of this disease. He did not think physicians should think of taking pay for such noble work.

Dr. William B. Canfield said he had arrived at the port of Baltimore, from Europe, in 1886, and although there was a case of small-pox on board, there was a delay of about fifteen minutes only at quarantine, and all landed. A few weeks later small-pox broke out in a Western town, and it was traced to this steamer.

Dr. George H. Rohé could bring evidence of the efficacy of the disinfectants mentioned by him. He thought householders objected to reporting cases of infectious diseases on account of the inconvenience and expense of disinfecting. The government should do this.

SECTION ON ANATOMY, PHYSIOLOGY, AND PATHOLOGY.

Dr. Thomas S. Latimer read a paper on

REFLEXES,

in which he referred to the fact that reflexes were rarely absent in health, and often absent or exaggerated in certain diseases. He thought their study had grown in importance since the elaborate work of Lombard.

SECTION ON PSYCHOLOGY AND MEDICAL JURISPRUDENCE.

Dr. John S. Conrad read a paper entitled

HALLUCINATION AND ITS ALLIED STATES,

in which he ably discussed hallucinations, delusions, and illusions in the sane and insane.

SECTION ON MICROSCOPY, MICRO-CHEMISTRY, AND SPECTRAL ANALYSIS.

Dr. William B. Canfield presented a paper on

THE MICROSCOPICAL EXAMINATION OF URINARY SEDIMENT,

in which he dwelt more particularly upon blood, pus, epithelium, and casts in all their varieties, not omitting the details of the technique of searching for sediment, etc.

SECTION ON OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

Dr. Samuel Theobald, Chairman.

The Chairman read a paper on

THE INFLUENCE WHICH THE DISCOVERY OF COCAINE HAS EXERTED UPON OPHTHALMIC SURGERY,

in which he referred to its advantage in cataract, squint, and other operations on the eye, and as rendering more bearable applications of strong astringents on granular lids.

Dr. W. R. Monroe then presented a volunteer paper on

OXYGEN AS A THERAPEUTIC AGENT.

He reviewed the advantage of the use of oxygen in different diseases, and advocated its more general use by the regular profession.

(To be continued.)

NEW YORK NEUROLOGICAL SOCIETY.

Meeting held Tuesday Evening, April 3, 1888.

THE PRESIDENT, DR. C. L. DANA, IN THE CHAIR.

DR. A. D. ROCKWELL presented two cases of

BASEDOW'S DISEASE,

illustrating results which could not infrequently be obtained by treatment. The first case was that of a young lady who for a year and a half had presented the three symptoms—protrusion of the eyes, swelling of the neck, and increased frequency of the pulse. The neck had measured fourteen inches, and the pulse had varied between 140 and 160, or above. Respiration had been 35, as a rule. After four months of treatment, consisting of dietetic regulation, internal medication, and electricity to the neck, the size of the goitre had been reduced one inch, the exophthalmos had diminished, and the pulse had diminished 60 beats. The patient's whole physical condition also had been changed, so that she could engage in the occupations and the enjoyments of life. At the end of treatment the pulse was 75 or 80. It had intermitted from the first, and it still retained this characteristic. Five years had elapsed since the discontinuance of treatment, and there had been no relapse.

The second case was that of a gentleman still under treatment. Out of thirty cases in the speaker's experience this was but the second in which he had encountered the disease in the male. The case was of an incomplete type. Great improvement had followed treatment.

DR. W. M. LESZYNSKY presented a case of

ACUTE IDIOPATHIC NEURITIS OF THE BRACHIAL PLEXUS,

and read a paper embracing the history of the case, with carefully recorded electrical tests.

The patient was a man who had had an attack several years before, causing a painful and wasting paralysis of the right shoulder. This was followed recently by a second attack, involving the left shoulder. The areas of anæsthesia, local tenderness, and electrical reactions showed that nearly all the branches of the brachial plexus were involved. Syphilis, lead, and trauma were excluded.

DR. BIRDSALL, while acknowledging the difficulty of following the details of a written history, had the impression that the case presented was one of periarthritis, with neural involvement starting from the joint-disease. Dr. Jacoby had reported a number of similar cases.

DR. JACOBY was inclined to the same view; yet he had understood that there had been no antecedent-joint trouble either in the shoulder or the wrist.

DR. BIRDSALL added that in some cases the pain, the joint-involvement, and the paralysis appeared together. Especially in the case of the shoulder there was often no antecedent history of joint-involvement.

DR. DANA referred to Dr. Jacoby's article and asked whether the degeneration reaction had not been absent in his cases of arthritic paralysis.

DR. JACOBY replied that it had.

DR. BIRDSALL added that while this had also been the experience of Erb, in some of his own cases the degeneration reaction had been obtained.

DR. PUTNAM JACOBI asked how the electric resistance had been measured.

DR. LESZYNSKY replied that one electrode had been placed upon the hand, and the other upon the back of the neck. In reply to the objections, he stated that there had been no antecedent history of joint-trouble. At the time of the paralysis of the deltoid the patient could move the joint without pain. The suffering occurred in paroxysms, and with each paroxysm fresh paralyses developed. The circumflex was first affected, the paralysis of the deltoid occurring on the twelfth day, the supra-spinatus and infra-spinatus on the twenty-fourth day, and the triceps on the twenty-sixth day, after a very severe attack of pain which required a large dose of morphia and chloral for its relief. Later, the subscapularis and teres major had been affected, and last the biceps, upon the forty-fifth day of the disease. Repeated examinations of the condition of the joints had been made, and the possibility of joint-affection had been excluded.

DR. GIBNEY had had the case under observation, and had been unable to arrive at any decision in regard to it.

DR. M. ALLEN STARR presented a paper upon

SYRINGOMYELIA, ITS PATHOLOGY AND CLINICAL FEATURES, WITH EXHIBITION OF SPECIMENS, A STUDY OF A CASE, AND REMARKS UPON ITS DIAGNOSIS.

Syringomyelia is a condition of the spinal cord in which abnormal cavities are present within the organ. The cavities are of two kinds: First, a dilatation of the central canal—hydromyelia. Of this two specimens were shown, in each of which the cavity was easily seen by the naked eye and the complete epithelial lining was visible under the microscope. The tissue around the dilated canal was normal. Secondly, a destruction of elements of the spinal cord—syringomyelia. The first stage of its pathology is the infiltration of the spinal cord near the central canal with round cells, connective-tissue nuclei, or gliomatous cells. A specimen showing this condition was exhibited. The next stage is the production of a felt-like connective tissue with numerous nuclei through the spinal cord, but especially near the central gray substance, pushing aside or destroying the spinal elements. This gliomatous mass has a tendency to break down in its centre, leaving a fissure or cavity whose walls are formed by the felt-like connective-tissue mass. The formation of such a cavity is the third stage of the pathological process. Specimens were shown illustrating these three stages, the specimens being from Schultze's cases and obtained partly from Schultze and partly from his pupil, Dr. Van Giesen. In some specimens the cavity was wholly independent of the central canal, which was pushed forward. In another the new cavity opened into the central canal, which appeared to have been dilated. In still others, no trace of the central canal was to be seen. The gliomatous infiltration about the cavity was evident in all the specimens. The size of the cavity varied greatly, from a small fissure to a large cavity around which only a thin rim of spinal tissue remained. The cavity in some cases extended only through a few segments of the cord. In other cases it reached through its entire length. A diagram was shown representing its extent in a horizontal section of the spinal cord, the cord being divided into squares, and forty-eight cases being tabulated. The number of each case being placed in every square affected in the case, the greater number of squares numbered about the central area of the cord indicated the frequency with which this area was involved. The lower cervical and upper dorsal regions of the cord were the parts most frequently affected. The contents of the cavity is usually serous fluid, but may be bloody or thick and hyaline.

The clinical features of the disease were presented by means of a collection of typical cases accompanied by autopsies. They were found to be, first, progressive muscular atrophy with paralysis affecting some or all of the muscles of one limb, and usually extending to the opposite limb and to the trunk, sometimes attended by reaction of degeneration in the paretic muscles; secondly, vasomotor and trophic disturbances in the affected limb, consisting of cyanosis, coldness, bullous eruptions, ulceration, and abscess, and even atrophy and fragility of the bones and a diminution in the excretion of sweat; thirdly, peculiar sensory disturbances, consisting of a loss of the sensations of pain and temperature in the atrophied part, while the senses of touch, pressure, and location were preserved.

The distribution of these symptoms in accordance with the situation of the lesion in the cord was then fully discussed. In half the cases cited the anterior horns were involved and paralysis with atrophy was present. In two thirds of the cases the posterior horns were involved, and the peculiar sensory disturbances were observed.

A case was then related in which the characteristic symptoms were present and in which the diagnosis of syringomyelia had been reached by exclusion, all other forms of spinal disease having been shown to be impossible. The differential diagnosis from amyotrophic lateral sclerosis, tabes, anterior polio-myelitis, meningitis, intraspinal tumor, and neuritis was considered in connection with this case. The paper closed with a reference to the etiology and treatment of the affection, regarding which little seems to be known.

Dr. Shaw said that about five weeks previously he had been consulted by a man, a German stevedore, who by his occupation was much exposed to the cold. The patient's complaint had been that he was unable to feel and protect himself from anything hot. The anæsthesia was especially marked in the right hand, but was present to some extent in the other also. As in Dr. Starr's case, there had been a burn on the right arm near the wrist, for which the patient could not account. There was no ataxia, no atrophy. There were no pupillary symptoms, and the optic nerve was normal. It seemed to him that this might have been a case of cavity of the cord similar to those of the cases described. He inquired, however, whether the origin of the condition was invariable. Might we not, for instance, have a cavity in the cord from malacia secondary to caries of the spine?

Dr. Sachs had been interested in the subject for several years. He had looked up the literature in connection with that of tumors of the cord, and he had also seen a number of living cases diagnosed by Schultze in Heidelberg. The clinical phenomena in Dr. Starr's case resembled those in Schultze's cases without doubt. He inquired, however, whether diagnosis between syringomyelia and intramedullary tumor was not difficult, especially at an early date. The duration of the condition would give a decisive indication at a later stage, as intramedullary tumors seldom lasted as long as two or three years. The difficulty of diagnosis was further increased by the fact that the symptoms so much resembled those of progressive muscular atrophy that the sensory manifestations might easily be neglected in favor of this diagnosis.

Dr. Birdsall recalled, from his own experience, three cases presenting motor symptoms of the atrophic type, vaso-motor and some sensory symptoms, which he thought might be due to cavity in the cervical portion of the cord; he had not yet arrived at an exact conclusion in the matter. There had been in these cases, too, cessation in the advancement of the disease. More careful observations would, he thought, lead to less frequent diagnoses of the typical or system diseases. There would be found many combinations of symptoms which did not correspond to these types. The system diseases, too, probably required to be divided up.

Dr. Booth recalled a case of marked atrophy of the arm and hand with anæsthesia, so that burns were not felt.

Dr. Putnam-Jacobi referred to the fact that in the cases cited a gliomatous tumor had served for the inception of the condition. She asked whether all cases of syringomyelia were referred to this origin. She also referred to the existence of vacuoles in the cord in pseudo-hypertrophic paralysis, in the medulla in tetanus, and in the condition of porencephalia in the brain. In five cases of pseudo-muscular hypertrophy there had been found dilatation of the central cavity or cavities in the posterior horns, although the correlation of the lesion with the paralysis had not been established.

Dr. Peterson referred to a case at the Manhattan Hospital where, in 1878, Dr. Seguin had diagnosed cavity of the cervical enlargement of the cord. The patient had presented atrophy of the left hand and arm with anæsthesia of the left arm, thorax, and leg.

Dr. Dana suggested that many cases diagnosed cervical pachymeningitis should probably have been classed as cases of this disease, as in Wichman's case. Dr. Starr had assumed that all cases of syringomyelia were gliomatous in origin. Might we not have cavity-building from some other cause: He showed a specimen in which similar cavities had resulted from a central myelitis. There had been two cavities in this case, one one and a half inch long and the other not so large.

Dr. Starr closed the discussion. The stationary condition in his case could be explained by the fact of the glioma having broken down and advancement having ceased. The process had been arrested. It was not possible to diagnose between intramedullary tumors and syringomyelia except as had been suggested by the duration of the case. The lesion had been discovered accidentally in all of the cases cited. The same had been true of multiple sclerosis in its first recognition. Then it had been diagnosed by exclusion, all cases not presenting typical symptoms being referred to it. Now syringomyelia received consideration also in the diagnosis of the anomalous cases. It might be of assistance to bear in mind that 24 out of the 56 cases had presented cavity in the anterior, and 32 out of the 56 cavity in the posterior part of the cord. The chances were therefore in favor of the symptoms of progressive muscular atrophy or accidental analgesic areas. In the examination it was necessary to distinguish between analgesia without loss of the temperature-sense and general anæsthesia. Intermissions were not uncommon in other conditions. He had seen the ataxia disappear, and return after several months. The reaction of degeneration did not appear to be an important diagnostic point. The majority of the cases had been diagnosed as progressive muscular atrophy, a condition in which this reaction was not found. The condition of porencephalia referred to was a condition of childhood and fœtal life; he did not think that it was ever found in the adult. The age of the patients with syringomyelia had been twenty-five to forty years. In all of the cases observed the previous state had been that of infiltration with gliomatous cells. Destruction did not occur during this stage; the elements of the cord were simply displaced.

Creolin in Cystitis.—In a very persistent case of cystitis occurring in a middle-aged woman, where the pain was so constant that the patient was generally obliged to keep her bed, and where the urine was offensive, brownish, and thick, depositing a third of its volume of pus, blood, and phosphates, after a large number of different kinds of treatment had been employed by various medical men without much result, the best application appearing to be injections of corrosive sublimate in very weak solutions, Dr. Jefsner washed out the bladder with a one-half per cent. solution of creolin. This caused a burning sensation for a few minutes, after which it passed off. The next day the patient felt and looked quite a different woman, the pain in the bladder had been less than for a long period previously, and the urine, when drawn with the catheter, was scarcely offensive at all, and appeared quite clear, depositing after a time only a small quantity of phosphate without any admixture of pus- or blood-corpuscles. The washing out of the bladder was repeated daily, and by this means the improvement was maintained. It would appear therefore that in creolin we have a deodorizer and a hæmostatic, as well as a means of improving the character of the secretion from the surface of mucous membranes. —*The Lancet.*

Hume and Diarrhœa.—David Hume wrote to the Countess of Boufflers, just before his death, and this note is supposed to be the last ever written by the great historian: "My distemper is a diarrhœa, or disorder in my bowels, which has gradually been undermining me for two years; but within these six months it has been visibly hastening me to my end. I see death approach without any anxiety or regret. I salute you for the last time. —David Hume."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ARMY MEDICAL DEPARTMENT AND ITS GRIEVANCES—MEDDLING AND MUDDLING AT HEADQUARTERS—REORGANIZATION OF THE MEDICAL STAFF CORPS—A REMARKABLE CASE OF RENAL CALCULUS—NEPHRECTOMY AND ITS DISADVANTAGES—FEMALE CANDIDATES AT THE SOCIETY OF APOTHECARIES.

London, April 14, 1888.

Considerable discontent is still being felt in the Army Medical Department, and, I may add, expressed as openly as the official regulations will allow. There does not seem the slightest probability of confidence and satisfaction being restored until some acceptable settlement of the question of rank has been made. Army medical officers feel much more strongly on the point than medical civilians can possibly do. From all I can learn I believe a very large proportion of army surgeons are in favor of some approximation to the system in force in the United States Army. No little apprehension has been excited among the Medical Staff by the issue of the warrant establishing an Army Medical Reserve. It is feared that this may gradually lead to an extension of the period of foreign service, which already averages about half the total period of service in the case of medical officers.

The meddling and muddling at headquarters appears to have now extended into the department of the Army Hospital Corps, or, as it is now termed, the Medical Staff Corps. In future, men will only be allowed to enlist for a period of twelve years, of which period, moreover, only four (in many cases only three) will be spent in actual service. The remainder of the time will be spent in the reserve. The effect of this regulation will be to largely augment the numbers of reserve men by increasing the number of men passing through active service in a given time. Presumably, it is supposed by the authorities that the larger reserve thus available will be of great service should we have the misfortune to become engaged in war. I leave it to your readers to imagine whether even well-trained and skilful nurses will be of much assistance if recalled to hospital duty after having left the wards for years, and been engaged in earning their living as carters, ploughmen, etc., as I have known many of them do. The short-service system has not answered so well for the combatants that it is desirable to extend it. At any rate, in the Egyptian campaign Lord Wolseley took good care to send only picked men. The number of reserve men receiving pensions is also largely increased, and thus to some extent the gibe at "Lord Wolseley's cheap soldiers" is justified. Bandsmen are specially exempted in the recent general order restricting the term of service, from which we may conclude that the authorities recognize the value of a trained musician if not that of a trained nurse.

A somewhat remarkable case of double nephro-lithotomy was narrated at length by Mr. Herbert Page, Surgeon to St. Mary's Hospital, at the last meeting of the Medical and Chirurgical Society. The patient was a man, twenty-two years of age, who had suffered for ten years from left renal pain, with occasional attacks of renal colic. For four years he had suffered from irritability of the bladder and had passed gravel. A year before admission a small calculus was removed from the bladder by lateral lithotomy. Pain in the left loin, however, recurred, and the urine contained pus and sometimes blood. His general health was much impaired at the time of his admission (in November, 1886). Mr. Page diagnosed vesical calculus and left calculous pyelo-nephritis. The vesical calculus was removed by median lithotomy, and eleven days later the left kidney was exposed in the loin and two small calculi removed from a suppurating cyst. No sensible diminution of the amount of pus passed took place, and some weeks later right renal pain was complained of. It was suspected that the pus came from the right kidney. Two or three weeks later severe right renal pain was complained of. Rigors and vomiting occurred, and the temperature rose. The pus almost entirely disappeared from the urine, and the amount of the latter fell from forty-two to twenty ounces daily. It was believed that this smaller quantity of urine was furnished by the left kidney only. The symptoms underwent aggravation and there was fulness in the right loin. A further operation was accordingly determined on, and the right kidney was exposed. It was found to be much enlarged and was surrounded by fetid pus. There was an opening in the pelvis from which Mr. Page thought it probable that an abscess had burst into the perinephral tissue. No calculi were found. The patient did well after the operation. The urine gradually increased in amount, while the pus steadily diminished. The patient lost all pain. He left the hospital three months after the last operation, and within a few days passed four small stones *per urethram.* He then steadily progressed to complete recovery.

Mr. Page remarked that the case was of interest from its bearing on the question of sympathy between the kidneys. He suggested that the right kidney had contained calculi for some considerable time, and that its condition was only revealed by the operation on its fellow. As time proved, nephrectomy would have been a very wrong thing, but had an abdominal exploration been made, it would probably have led to the performance of nephrectomy, for he would have found an apparently useless left kidney, and a right kidney so enlarged as to be presumably fit for future needs, and its calculi, being small, would most likely have escaped detection. Had a nephrectomy been performed, the position of the patient at the time when the functions of the right kidney were presumably in abeyance would have been infinitely more grave.

Mr. Godlee concurred in the opinion expressed by Mr. Page as to the advisability of not performing nephrectomy. He thought it wise at the time of excision of a stone to leave the kidney from which it was taken, for it might heal, or, at any rate, would contract, and thus be more easily removed, should its removal be afterward found necessary. In a case cited by Mr. Page where renal calculus followed hysterectomy, it was a question whether the operation of hysterectomy really led to the formation of a stone or only set up inflammation around a stone already existing, and thus caused its presence to be revealed. He thought the first hypothesis very probable, considering how frequently stones appeared to result from accidental injuries, such as being run over by a cart-wheel, etc.

Another portal has been provided for women who wish to enter the medical profession, for the Apothecaries' Society of London has determined to admit them to examination in future. One lady has just been admitted to examination. In 1865 Mrs. Garrett Anderson (now M.D., Paris) was allowed to present herself for examination, and received the diploma of L.S.A., but since then no others of her sex have been allowed to present themselves for examination until now. A new departure is, therefore, being taken by the Society.

FOR THE CURE OF WINTER ITCH.

To the Editor of The Medical Record.

Sir: I have been treating so-called "winter itch" for twenty-five years. The first epidemic I saw was in Sherman's army, in 1864–65. It is the king of pruritus, and should be designated in nosology as prurigo major. The only eruption that is characteristic of it is papular; the eczema and others are accidental. I have always regarded it as a neurosis. The worst case I have ever seen occurred in June. It is the attendant of a dry atmosphere, commencing early in the high lands, and extending to the valleys as winter advances. Great numbers of the early cases get well in December and January, even if not treated.

The base of successful treatment is in atropine dissolved in glycerine, which should be rubbed into the skin until itching ceases. This should be done with the palm or some smooth rubber. The less scratching with the fingernails the better. I use fluid extract of belladonna, ʒ ij., to glycerine, ℥ j. This frequently fails, but I can cultivate its successful use in many of the so-called failures, when opportunity affords to school the patient, and the apt ones have very few failures. It may be necessary to repeat nightly, or indefinitely; but a patient who has some experience with the disease will be very tractable when he finds the persistent rubbing will allay the itching. Frequently there is no return of it for the night, after once subduing it.

A variety of combinations to suit cases which are obstinate, such as aconite, carbolic acid, or chloral and camphor may be added, or hyoscyamus substituted; or to suit those cases with eczema or scabies; or to kill acarus or pediculi. But this is the province of the "busy practitioner," other than the simple mention of which, in a brief paper like this, would be superfluous.

Joseph A. Stilwell, M.D.

Brownstown, Ind., April 20, 1888.

New Instruments.

A PHOROMETER.

By GEORGE T. STEVENS, M.D.,

NEW YORK.

This instrument is designed to assist in the determination of the relations of the visual lines to each other.

Experience long since led me to observe that the method of determining the relative tendencies of the visual lines in respect to the horizontal plane by means of prisms held in the hand, or fixed in the ordinary trial frames, is an extremely imperfect one, adapted only to the rudest measurements. Two years ago I had constructed spectacle-frames in which were placed oblong quadrilateral prisms for the determination of hyperphoria. The form of these hyperphoria trial spectacles, by their rectilinear outline, enabled the examiner to determine their approximate relation to the horizontal plane.[1]

Further experience showed that the difficulty of adjusting the head of the patient was, in a considerable number of cases, attended with difficulty, and, at the best, the adjustment of both head and glasses was, to a certain extent, inexact. This led to the introduction of the spirit-level as an indicator of the position of the prisms. It was found that the attachment of the level to the spectacle-frames presented little advantage, owing to the difficulty of maintaining a perfectly erect position of the head. I observed that if the prisms were placed upon an independent support and removed a few inches from the face, it mattered little if the head is not held with perfect accuracy, and that in most cases it might be carried far over to one or other side without altering the relations of the double images to each other or to the horizontal plane. The result of these observations was the phorometer which is here figured.

The instrument consists of the standard A, supported by a tripod. The standard is freely extensible, permitting a ready adjustment for differences in stature of patients. The arm B is grooved, and allows the carriers C and D to rest securely, to slide freely from end to end of the arm, or to be removed at will. At E a spirit-level is attached to the arm, by means of which the horizontal position of the arm can be determined. The semicircular piece at the head of the arm is spirally toothed and is acted upon by the endless screw at F, which imparts to the arm an upward and downward elbow movement. The semicircle is graduated in degrees, and a fine pointer indicates the extent of motion imparted by the screw. By means of the lever G, the screw can be unlocked, allowing the arm to fall to the side of the standard. Of the two prism-carriers one carries two prisms placed horizontally, with their bases in, and of sufficient strength to induce homonymous diplopia. The prism D is placed with its base down and is used for determining lateral tendencies. The rod H carries a tablet I, on one side of which is a small cross and on the other side another cross somewhat larger. The tablet is reversible, and the crosses are used as objects in determining the tendencies in accommodation. The tablet is, when brought into position, one-half metre in front of the prism; but by means of a fixation-screw it can be brought nearer if desired.

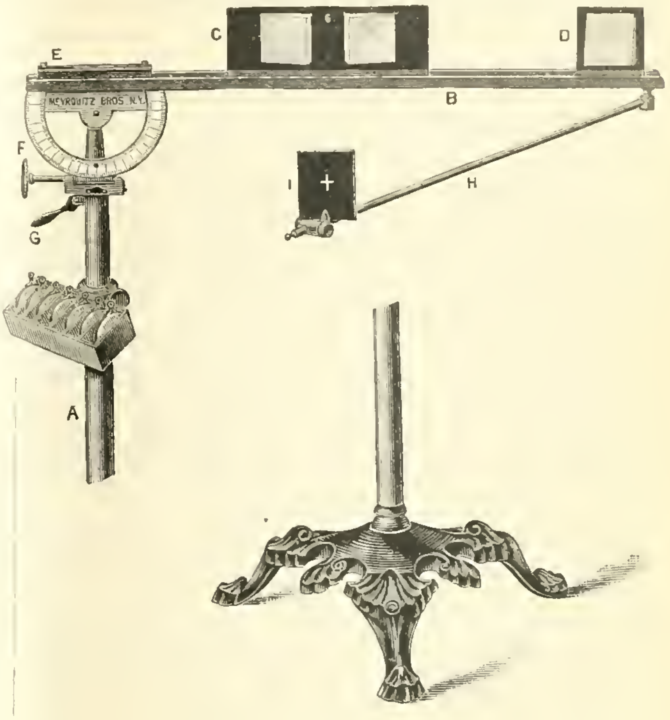

Fig. 1.

When not in use the rod is parallel with the arm. As has been intimated above, in the determination of the tendencies of the visual lines much freedom may be given to the position of the head without material effect upon the position of the images, provided the prisms are independent of the head and somewhat removed from the eyes. This does not hold good in every case, but the exceptions are somewhat rare, and the presence of the exceptional condition can be quickly ascertained.

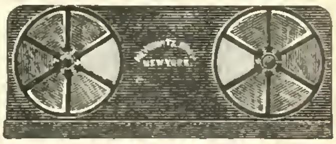

Fig. 2.

Fig. 2 represents a pair of revolving disks in a carrier adapted to the phorometer; each disk consisting of six prisms with the bases in. The two openings permit the two eyes to see from behind. By pressing upon the milled edge of either disk, prisms of different strength can be brought before the openings. The numerals in the figure show the strength of the various prisms. This little device I find very convenient and time-saving in the determination of the power of abduction. A series of prisms for adduction is similarly constructed.

I have now used the phorometer during several months past, and find that it not only insures greater accuracy in the examination of the relations of the ocular muscles than is easily obtained by other methods, but it enables the examiner to perform his work with much greater expedition than when it is done by the usual methods.

---

[1] Notwithstanding the fact that these trial spectacles were described in several medical journals and that they had been manufactured by several instrument-makers from the pattern furnished by me, they were recently figured in this journal as the device of another.

The instrument is manufactured by Messrs. Meyrowitz Brothers.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 15 *to April* 28, 1888.

STERNBERG, GEORGE M., Major and Surgeon. Having been instructed by the President to proceed to the Island of Cuba, for the purpose of continuing his investigations of the methods of preventing the spread of epidemic diseases, will, in connection with his present duties, report to the Secretary of the Treasury for further instructions. S. O. 89, A. G. O., April 18, 1888.

EWEN, CLARENCE, Captain and Assistant Surgeon. Granted leave of absence for six months, with permission to go beyond sea. S. O. 85, A. G. O., April 13, 1888.

ARTHUR, WILLIAM H., Captain and Assistant Surgeon. Ordered from Fort Niagara, N. Y., to Fort Bowie, Ariz., to take effect on the expiration of his present leave of absence. S. O. 86, A. G. O., April 14, 1888.

BLACK, CHARLES S., First Lieutenant and Assistant Surgeon. Ordered from Fort Davis, Tex., to Fort Sidney, Neb. S. O. 86, A. G. O., April 14, 1888.

The operation of Par. 17, S. O. 79, c. s., A. G. O. (so much thereof as relates to Captain GEORGE E. BUSHNELL, Assistant Surgeon, U. S. Army), is suspended until May 1, 1888. S. O. 90, A. G. O., April 19, 1888.

CROSBY, WILLIAM D., First Lieutenant and Assistant Surgeon. Ordered for duty at Jefferson Barracks, Mo., after being relieved by Assistant Surgeon William H. Arthur, and upon the expiration of the leave of absence granted him in S. O. 60, A. G. O., March 14, 1888. S. O. 86, A. G. O., April 14, 1888.

RAFFERTY, OGDEN, to be Assistant Surgeon, with rank of First Lieutenant, March 26, 1888.

GIRARD, JOSEPH B., Captain and Assistant Surgeon. To be Surgeon, with the rank of Major, March 22, 1888.

BAILY, JOSEPH C., Lieutenant-Colonel and Assistant Medical Purveyor. Granted leave of absence for twenty days on Surgeon's certificate of disability, with permission to apply for an extension. S. O. 92, A. G. O., April 21, 1888.

BAILY, J. C., Lieutenant-Colonel and Assistant Medical Purveyor. Will transfer the public funds for which he is responsible, and the charge of the medical purveying depot in New York City, temporarily, to Captain Henry Johnson, Medical Storekeeper. S. O. 92, A. G. O., April 21, 1888.

Par. 13, S. O. 89, A. G. O., April 18th, is revoked by Par. 1, S. O. 93, A. G. O., April 23d, and Major GEORGE M. STERNBERG, Surgeon, U. S. Army, is directed to proceed to the Island of Cuba, for the purpose named in the letter of the President, addressed to the Secretary of War, on the 17th inst. Upon the completion of this duty, will return to his proper station, and submit his report to the President on or before June 25, 1888.

VICKERY, R. S., Major and Surgeon. Granted leave of absence for four months, with permission to apply for an extension of two months, and to go beyond sea. S. O. 95, A. G. O., April 25, 1888.

By direction of the President, Surgeon Remus C. Persons, U. S. Navy, is assigned, temporarily, to the charge of the Army and Navy General Hospital, Hot Springs, Ark., during the absence, on leave, of Major Richard S. Vickery, Surgeon, U. S. Army, Surgeon-in-Charge. S. O. 96, A. G. O., April 26, 1888.

WOOD, LEONARD, First Lieutenant and Assistant Surgeon. Granted one month's leave of absence, with permission to apply for an extension of two months. S. O. 41, Dp. Ariz., April 18, 1888.

ANDERSON, CHARLES L. G., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence from June 1, 1888. Resignation accepted by the President, to take effect July 1, 1888. S. O. 92, A. G. O., April 21, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 28, 1888.

RHOADES, A. C., Medical Inspector. Detached from special duty, New York, and waiting orders.

HENNEBERGER, L. G., Passed Assistant Surgeon. Detached from Naval Hospital, New York, and to special duty attending officers and families, New York.

OBERLY A. S., Medical Inspector. Granted six months' leave, with permission to visit Europe.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 28, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	2
Scarlet fever	221	35
Cerebro-spinal meningitis	4	3
Measles	88	9
Diphtheria	172	43
Small-pox	14	5
Yellow fever	0	0
Cholera	0	0

THE WORK OF THE BLOOD-CORPUSCLES IN THE ANIMAL ECONOMY.—In the course of a recent address on "The Struggle for Life," Dr. Ray Lankester said (*The Hospital Gazette*) that the corpuscles could be educated to deal with the bacteria, and the future of preventive medicine would be the education of the white blood-corpuscles. The fact that one man, by constant use, could without injury take a dose of arsenic that would kill six ordinary men, was due to the fact that he had by weakened doses been educating and training the white corpuscles. They could be taught to eat and flourish under conditions which, if not commenced gradually, would be destructive to them, and that was the principle underlying protective inoculation. As a preventive of many fatal diseases in sheep and oxen, inoculation had been remarkably successful. The corpuscles first received a weakened breed of disease by inoculation, and thus when a violent attack came they were ready to receive and dispose of it. This education of the corpuscles, it seemed to him, was the explanation of the success of vaccination. They received a weak dose of the poison from the vaccine, and were in that way prepared for a stronger dose in the way of small-pox. He believed the white corpuscles could be trained to receive the most virulent poisons, and he hoped this training would be carried on so as to deal with a great number of diseases.

A CONGRESS OF HYGIENE was held in January last, in Lima. Delegates attended from Peru, Bolivia, Ecuador, and Chili.

THE CORONER of Baltimore is to be congratulated upon an increase of fifty per cent. in his salary. He now receives $900 per annum.

THE *Hartford Courant* devotes a column a week to medical items of popular interest.

EXPERIMENTAL OBSERVATIONS ON LITHOLYSIS.[1]

By HERMAN GOLDENBERG, M.D.,

NEW YORK.

EVER since anything has been known concerning urinary calculi, attempts have been made at dissolving them by means of internal medication: Teas, medicaments, and mineral waters. Most of these were the outgrowth simply of empiricism, a rational basis being first obtained after a knowledge of the chemical constituents of urinary calculi was arrived at, and the proper agents for dissolving them, theoretically, at least, were known.

Attempts to tabulate the solubilities of uric acid and uric-acid stones are of old date. They were originally made by showing the effect of mineral waters and medicaments on the calculi in the test-tube. The results thus obtained did not correspond with those of clinical observation. There arose, in consequence, among practitioners, a pessimistic view in regard to the use of internal remedies on already formed calculi. Owing to this, and also to the progress of surgical treatment of stone, in course of time only a proper hygiene and diet, as well as internal medication for the prophylaxis thereof, were resorted to.

In order to arrive at a clear therapeutic notion in regard to the agents used for this purpose, it will be of value to establish in what manner each remedy acts, the relation of one remedy to another, and, furthermore, which one is suited to the individual case. As I mentioned before, many experiments have been made to determine the effect of mineral waters on uric acid. Jahns, of Göttingen, together with Ebstein, not long since made such investigations. They have not, however, a great practical value, as Ebstein himself points out in his book on calculi, because we are not justified in drawing conclusions from the effects in the test-tube to what may occur in the human body. As, for example, lithium carbonate when brought in direct contact with uric acid dissolves it readily, whereas, on being introduced into the body the greater part of it becomes changed in the stomach by the gastric juice into a chloride, and appears as such in the urine, displaying scarcely any power in dissolving uric acid. In order to produce an effect it would have to appear in the urine in the form in which it was introduced.

Emil Pfeiffer was the first to formulate the matter properly, by investigating the influence of the urine obtained after the employment of mineral waters and internal medicines upon uric acid. At the Fifth German Congress for Internal Medicine, at Wiesbaden, this question was broached by him. He presented the results of his investigations, which were limited to representatives of three groups of mineral waters, viz., the alkaline sulphate waters of Carlsbad, the sodium chloride of Wiesbaden, and the pure alkaline of Fachingen. The investigations concerning the Carlsbad spring showed that during its use the urine exhibited a considerable solvent action on uric acid, and that not only did this action cease on stopping the use of the waters, but even the opposite effect was produced. The same is to be said of the Wiesbaden springs, whose solvent power is even less than that of Carlsbad. The Fachingen waters showed themselves the most powerful solvents. The urine during the use of these waters (Fachingen) causes, according to this writer, "the rapid solution of uric-acid calculi, and the after-effect, as compared to that of the other springs, is more lasting." The great practical importance of these results led me, in conjunction with Dr. Posner, of Berlin, in the laboratory of Lassar to pursue somewhat similar investigations.

Our investigations embraced also other springs and internal medicaments. We did not confine ourselves to experimenting with the effect upon chemically pure uric acid alone, as Pfeiffer had done; but endeavored, in order to more closely approximate physiological and pathological conditions, to extend our observations so as to include powdered calculi, gravel, fragments, and fully formed stones. For a similar reason, urine kept at the temperature of the body was employed. The urine employed was obtained from subjects in Lassar's Clinic for Skin Diseases, who were not suffering from any constitutional affection, and from the writer, after using the mineral waters and medicaments whose effects were to be studied. The usual manner of living and diet were not changed during this period.

A known quantity of dried uric acid, or uric-acid concretions, was placed upon a filter whose weight had been determined after drying. Two hundred cubic centimetres of the urine in question, carefully filtered, were poured upon this; the filter was then washed with distilled water, and its weight again determined after drying. The difference in weight would show, of course, the amount of uric acid dissolved.

As a control, similar experiments were made with normal urine, *i.e.*, urine obtained from individuals who had not been taking any of the medicaments whose action was to be investigated. We found that not only did this urine have no solvent effect on the uric acid in the filter; but, on the contrary, uric acid was deposited from it on the filter, and, indeed, the higher its specific gravity the greater was the quantity of uric acid thus deposited.

As a detailed description of our experiments appeared in the thirteenth volume of the *Zeitschrift für klinische Medicin*, I will confine myself to a brief statement of our results, and the deductions to be made from them.

The "Désirée" Spring of Vals, which is much used in France for gout, uric-acid diathesis, etc., proved the most efficacious; 100 c.c. of urine obtained after the daily administration of one bottle of Désirée was found capable of dissolving about one decigramme of uric acid.

The "Grand Grille" of Vichy possesses nearly the same power. Then follow Fachingen, the Helenenquelle of Wildungen, and, finally, Obersalzbrunn Kronenquelle. The latter, for example, has only one-fifth the solvent power of the Désirée.

Pfeiffer assumed the existence of a relationship between the solvent power of the mineral waters and their percentage of sodium carbonate, which fact we confirmed in our experiments. Vals, the most efficacious, contains six parts per thousand; Vichy, five; Fachingen, four; etc. Concretions of uric acid were less powerfully acted upon by the urine obtained after the use of these waters than the pure uric acid.

Powdered uric-acid concretions and gravel were acted upon somewhat; to only a slight degree, the semispherical fragments of a uric-acid calculus of the size of a cherry-stone. The effect on solid calculi was somewhat limited. A calculus wrapped about with mull gauze put into a beaker glass filled with filtered Fachingen *water* was, after twenty-four hours, reduced to a soft, friable mass. The effect of the *urine* obtained after the use of Fachingen was quite different; a loss of weight was found, however. For example, a stone weighing 97 milligr., after six days' treatment with such a urine, which was renewed daily, showed a loss in weight of 5 milligr.; a change in structure was not apparent, the stone remaining as hard as before; only slight erosions were to be noticed on using a lens.

---

[1] Read before the Medico-chirurgical Society of German Physicians of New York, March 5, 1888.

Pfeiffer's statement, that urine obtained after the use of Fachingen water dissolves uric-acid calculi very rapidly, is to be regarded as too sanguine, it being true only of the smallest concretions, or, rather, gravel.

Urine obtained after using Vals was most effective. After a two days' use of a bottle daily of Désirée (Vals) water, the urine rendered previously hard stone fragments soft and friable.

Since there could be no doubt that the solvent effect of the mineral waters must be ascribed partly to chemical action upon the urine (which point I will refer to later), it seemed of importance to study the individual constituents of the various springs.

After we found that the effect of the waters is due chiefly to the sodium carbonate contained in them, we gave it in quantities corresponding to those contained in the more powerful mineral waters. In doses of 5 gm. daily, dissolved in a suitable quantity of water, so as to imitate more closely the giving of the waters themselves, the result approximated that following the use of Fachingen. Such doses produced disagreeable effects upon intestinal peristalsis, and, through strongly alkalinizing the urine, brought about a precipitation of phosphates, causing vesical irritation.

Similar effects were produced by Cantani's powder, composed of lithium bicarb. 1, sodium bicarb. 2, potassium citrate 4. Also, to somewhat less degree, by magnesium boro-citrate, which, however, is well borne in long-continued doses. A patient suffering from renal colic used the latter systematically, during several weeks, with excellent results. The least effectual of the remedies employed by us was borax, a drug which became celebrated through the classical instance of the case of Virchow, who was cured by its use of gouty kidney.

Lithium carbonate is a remedy now much in vogue. Of late years much opposition has arisen against it on account of the toxic action on the heart, and also because, according to Ebstein, the greater part of it appears in the urine in the form of a chloride which does not dissolve uric acid. Without going into the question more closely, I would state that this salt was found by us to possess a decided solvent action. In daily doses of 6 dcgr. of lith. carb. the effect of the urine upon uric acid is almost equal to that after the use of Fachingen. It has, however, the disadvantage of being entirely excreted from the urine within twenty-four hours. In consequence, there is no after-effect produced.

Before drawing my conclusions from the above-mentioned experiments as to the treatment in practice of these diseases, I may be permitted to add a few words as to the nature and etiology of uric-acid calculi, and the action of the remedies to be employed, in order to find a rational basis for treatment.

It was formerly thought that calculi are formed simply by crystallization from concentrated solutions, the individual crystals becoming apposed to each other. In other words, the process is analogous to the deposit of uric-acid crystals in concentrated urines after evacuation from the bladder. Later investigations, especially the elaborate studies of Ebstein, have shown that the pathological process in the formation of calculi is strictly analogous to the normal process in the development of the osseous system. In both cases we have an organic basis, within and about which sedimentation goes on (lime salts in the case of bone, uric acid, etc., in the case of calculi). The organic, non-crystalline structure of all concretions, even of the smallest gravel, can readily be demonstrated. In the formation of calculi we find, besides the organic basis, which is composed of albuminous material, originating in the kidneys or in the urinary tract, an abnormal condition of the urine, the expression of a disordered metabolism. These two factors stand in a causal relation to each other, in so far as an abnormal composition of the urine—whether due to an excessive amount of acid in general, or to an excess of uric acid in particular—acts as an irritant upon the mucous membrane of the uro-genital tract, which, continued a long time, is apt to cause an epithelial desquamation, thus favoring the formation of an organic structure for the calculus.

We see that the formation of stone depends on both local and general causes; a third factor is found in a mechanical cause—an obstruction in the urinary apparatus. These three factors are essential; the uric-acid diathesis is only subsidiary. Too much weight is usually attached to the importance of this diathesis in the formation of stone. If the other elements do not accompany the uric-acid diathesis, calculi will not be produced, but only crystals of uric acid.

In the treatment we must take into account the above-mentioned etiological factors. It must be prophylactic or curative, general or local, internal or surgical.

I cannot here discuss local and surgical measures, my province being limited to the action and value of those internal remedies which answer the indications in the majority of cases.

If any of the above-mentioned mineral waters or medicaments are introduced into the body, their effect upon the urine finds manifold expression. The urine undergoes a chemical change, the excessive formation of acids is checked, its quantity is increased, and, in consequence, the specific gravity is diminished. The increased diuresis is not only of use mechanically, the uric-acid concretions being washed away by the greater amount of water, but the chemical action in these waters is better utilized. It is certainly not a matter of indifference whether, within a given time, a solution of only a few hundred cubic centimetres pours over the pathological products, or one of two litres, or more. The dilution resulting from increased diuresis favors greatly the chemical processes.

All these favorable influences are possessed in the highest degree by mineral waters. They exert a relatively intense chemical influence, and act most favorably in increasing and diluting the urine. They are our best resource in contending against catarrhs of mucous membranes, fulfilling the indications of which I have already spoken. Because of the chloride of sodium and carbonic-acid gas which they contain they are well borne by the stomach, and, in general, exert no deleterious action on the body.

In deciding, in a given case, upon the remedy to be preferred, the choice will depend upon what we wish to accomplish in that case. In an acute case we would employ the strongest remedies, particularly those waters containing the largest amount of sodium carbonate, viz., Vals and Vichy, and perhaps, also, Fachingen. Should there be an objection to using these on account of their relatively high cost, we may substitute the simple remedies, especially bicarbonate of sodium, in doses of 3–5 gm. daily, largely diluted, if possible, in carbonated waters. Lithium carbonate might also be employed in these cases, were it not that the long-continued use of this remedy is not free from danger, and that as soon as it is discontinued its action ceases. I would here warn against the long-continued use of the more powerful medicaments and mineral waters. If they are given for too long a period we are driven from Scylla to Charybdis—in place of the concretions of uric acid, phosphatic concretions will be apt to occur, or around a nucleus of uric acid the phosphates will be deposited.

In chronic cases, therefore, we should not employ the stronger remedies. We employ in these cases milder remedies, especially the Fachingen water, or the milder acid waters, namely, Kronenquelle, Bilin, Geilnau, etc. Of internal medicaments magnesium boro-citrate is to be preferred, since its use can be continued without danger for a long time. The prolonged use of Cantani's powder is, on account of the potash and lithium, not without danger.

No fixed rules can be laid down as to dosage. We have a guide in the condition of the urine in the given case. As soon as an alkaline reaction is found, we must discontinue the stronger medicaments, or rather avoid altogether its occurrence. In our experiments we obtained the greatest effect in those cases in which the reaction of the urine was slightly acid or neutral. As soon as the urine became distinctly alkaline, the solvent action began to diminish and ceased altogether when there was present an excess of phosphates. From this we may safely conclude a similar effect in the action within the body. In this respect the mineral waters present an advantage, because the carbonic-acid gas they contain favors the production of an acid reaction of the urine.

When Fachingen is to be given for a time, we may pause in its use for a day or two after having given it about four days. On using it for several weeks, we can without harm intermit in its use for a week at a time.

In determining the daily quantity to be taken we must consider the fact that the effect does not increase in proportion to the amount of the alkaline carbonates—twice the effect not being produced by giving a whole bottle instead of a half. The absolute effect depends particularly upon the degree of concentration. The daily quantity influences relatively by increasing the amount of urine. I would, therefore, recommend the use of a considerable quantity of ordinary water in addition to the mineral water.

I believe I have sufficiently demonstrated the solvent action of the medicaments mentioned upon uric acid. The question of how far we can act upon stones already developed is more difficult. That an effect upon them is not beyond the range of possibility, the experiments on gravel abundantly prove. We can confidently expect a solution of smaller calculi after giving the remedies for a sufficiently long time. On the other hand, as regards larger stones, I am inclined not to be too sanguine. Pfeiffer seems to have gone too far in his conclusions in declaring that Fachingen water dissolves calculi very rapidly. In one case, as before mentioned, after a two days' use of Vals Désirée water, the urine had such an effect upon gravel and stone fragments that they not only lost considerable weight, but also were rendered soft and friable. I would, therefore, call attention once more to the superiority of this spring, but I would not go so far as to conclude that this treatment would have any considerable effect upon fully developed stones of the bladder. We should not lose too much time with such attempts in a given case. The surgeon and physician should here work hand in hand. In a case of lithotripsy the Vals water might render great service in rapidly dissolving fragments which might be left behind.

Ebstein, in his concluding remarks in his book "On the Nature and Treatment of Calculi," speaking of the internal treatment and of the possibility of dissolving them, says that we can with certainty expect from the careful use of the alkaline waters a mechanical effect, and probably also a favorable influence upon the affected urinary organs. He admits the possibility of chemical solution, but rejects its induction altogether on account of the danger to the system of an alkaline *régime*. Far be it from me to underestimate the dangers of the introduction of an excessive amount of an alkali into the body; though convinced that there can be an abuse of the now much-used alkaline waters, yet I believe that their field of usefulness, as shown by experiment, is wider than we have a right to expect from what Ebstein says. The waters and some of the medicaments experimented with by us showed a decided effect in daily doses, such as are well borne in long-continued use. Used in a systematic manner, and with due regard to the limits set to the internal treatment of concretions, they will also in this connection preserve their high standing in the treatment of an excess of acid in gravel and calculous disorders.

107 East Fifty-ninth Street.

THE USE OF PROPRIETARY MEDICINES BY THE LAITY AND THE PROFESSION.[1]

By FREDERICK A. CASTLE, M.D.,

NEW YORK.

The invitation to address you on the subject of the relations of the profession and the public to the nostrums of the day, is capable of elaborate treatment or otherwise, according to the views of the writer and the time at his disposal. There can be no doubt that the subject is one which is well worthy of consideration; but my own feeling with regard to it is that, so far as the relations of the profession are concerned, the less physicians have to do with remedies about which they know little or nothing, the better it will be for their reputation and for the welfare of their patients. So far as relates to their use by the general public, the time has arrived when the influence of the profession, in the direction of repression, amounts practically to nothing.

Some time ago members of the medical profession were much too charitable in lending their aid in giving character to the few nostrums which then existed, and helped, in a great measure, to establish the foothold which this class of preparations long since gained in this and other countries. Like the snow-ball on a mountain's side, those who helped to start it on its course soon lost all control of it, and can only stand, as calmly as they may, and witness the avalanche which it has caused and the destruction which marks its track. Any opinion generally expressed by physicians of the present day, with regard to the harmful character of these articles, is pretty sure to be attributed by the public to a feeling of jealousy; and the more positive the opinion, the more convinced will the layman be that there must be some virtue in the thing after all has been said, or the doctors would not pitch into it so heartily.

There is such general misunderstanding of what constitutes a nostrum, that it appears to me to be desirable, before proceeding further, to explain in some detail the true nature of this class of commodities. As its name implies, a nostrum is something which is the exclusive property of some particular person or corporation. As applied to medicines, it practically embraces, in the United States, three classes of articles: Those made by a formula which is patented; those which bear a label, the specific design of which is registered in the Patent Office; and those sold under a trade-mark, which generally consists of a fanciful title, and which is similarly registered in the Patent Office, and held as the exclusive property of the person who causes it to be so registered. Formerly the number of patented formulas was relatively much larger than at present, but in course of time it was found more expedient to take advantage of the law providing for registering trade-marks. This was for a variety of reasons. In the first place, patenting a formula rendered it necessary to publish its ingredients, their proportions to each other, and often the process by which they were combined. This permitted any person who could improve upon the formula or process, as patented, to do so without peril; it being only requisite that some ingredient be substituted by another, or that some change be made in the method of composition, to evade the text of the patent. The original maker, however, was not so favorably situated, since it became essential that any change that he might desire to make must be similarly protected by patent right. Another reason was the fact, that the publicity necessarily given by the act of patenting a formula enabled many people to know its composition and judge of its merits, entirely irrespective of statements regarding its efficiency as a remedy by those who were interested in its sale. As soon, therefore, as the Government instituted the system of registering trade-marks, by which the person entitled to its exclusive use was protected from its use on the part of other persons, without regard to the exact nature of the article to which it might be applied, we had the conditions established which have favored the development of an enormous business in this class of articles. How extensive this business now is can best be understood from the following statements, made before the Committee on General Laws of the Assembly of the New York State Legislature, now in session. The authorities for this statement are manufacturers of proprietary medicines, who were heard by the Committee as opponents of a bill now before the Assembly, which, if enacted, would require all packages of proprietary medicines to be labelled with the exact nature of the contents, and would, moreover, prohibit the sale of such remedies in this State as had not been approved by the State Board of Health.

---

[1] Read before the Section on Laryngology of the New York Academy of Medicine, March 27, 1888.

According to this showing, in the State of New York there are one hundred and eight manufactories of patent medicines, employing capital amounting to $3,512,430, and putting out, annually, medicines valued at $4,339,178. In the whole United States there are five hundred and sixty-three manufactories of these goods, with a capital of $10,620,880, and an annual production valued at $14,682,492. This estimate is, I believe, rather short of the actual facts.

During the year 1886 the number of patents issued (including designs) was 22,392, of which only about two dozen were for medical compounds; 1,027 trade-marks were registered, 191 of them being for medicinal articles; 378 labels were also registered, 202 of them being intended for articles of a medicinal character.

As an indication of the proportion which articles nominally intended for treatment of conditions of the throat and nose bore to the others, it may be said that none of the patented formulas were of this character, and but twelve of the trade-marks and two of the labels. It may also be of interest to such of you as have had no occasion for studying the Official Gazette of the Patent Office, to listen to the short statements given in that work of the ingredients entering into some of the patented nostrums. Here are a half-dozen or so, taken rather hap-hazard, which will fairly illustrate the majority of them:

"333,746. Medical Compound. Rufus G. Gish, Redfield, Kans. Filed May 2, 1885. (No specimens.) *Claim*—The herein-described medicine for the treatment of consumption, etc., consisting of blood-root, dandelion, black cohosh, burdock-root, spikenard, comfrey, bittersweet, sassafras, water, sweet yeast, loaf sugar, and spirits, about in the quantities given.

"343,660. Remedy for Dyspepsia. Bernard Farley, San Francisco, Cal. Filed March 4, 1886. (No specimens.) *Claim*—The herein-described composition of matter used for dyspepsia, consisting of senna, manna, Epsom salts, aloes, molasses, cream tartar, ginger, licorice, and red pepper, in the proportions specified.

"347,759. Medical Compound. Silas W. Fleming, Steubenville, O. Filed April 23, 1885. (No specimens.) *Claim*—The herein-described composition or mixture of ingredients to form a medicine for diseases of the liver and lungs, consisting of the following ingredients: Spikenard-root, rattleweed-root, elecampane-root, ginseng-root, snake-root, sweet-anise root, spice-bush root, yellow parilla, catnip-tops, hoarhound-tops, mandrake-root, liverwort-tops, wild-cherry bark, yellow-poplar bark, white-oak bark, dog-wood bark, slippery-elm bark, boneset-tops, spearmint-tops, and balm-of-gilead tops, in the proportions specified.

"348,854. Remedy for Kidney Diseases. Nathan C. McCutcheon and Alexander T. McCutcheon, Springfield, O. Filed January 12, 1886. (No specimens.) *Claim*—The herein-described composition of matter to be used for the treatment of diseases of the kidneys in general, consisting of Scotch ale, scoparius, taraxacum, and celery, in the proportions specified.

"349,591. Medicated Lozenge. Alvah W. Holway, Boston, Mass. Filed August 25, 1885. (No specimens.) *Claim*—1. A tablet or lozenge consisting of sugar, cream of tartar, and acid calcium lactate, substantially as set forth. 2. A tablet or lozenge in which sugar and acid calcium lactate constitute a base, substantially as expressed.

"350,867. Remedy for Kidney Diseases. Frank E. Chadwick, Rochester, N. Y., assignor to the F. E. C. Medicine Company, same place. Filed April 22, 1886. (No specimens.) *Claim*—The herein-described remedy for kidney diseases, consisting of motherwort, barberry-leaf, couch-grass, winter-green, water, and gin, prepared in the proportions and manner specified."

We might be inclined to laugh at the polypharmacal character of some of these heterogeneous mixtures, were it not that the compounders were simply following the customs of our ancestors in the medical profession, who seemed to think that the more drugs they could crowd into a dose the more virtue it would possess as a remedy; or had we not in mind one of the medical colleges of this city, whose pupils take from the school a formula which, by its incongruity, serves to establish their *alma mater* about as effectually as the ear-mark designates the ownership of a stray cow on a Western cattle-ranch.

Of course, the greater part of the largest proportion of nostrums are used by the general public without regard to professional advice. and will continue to be so used, as I have before intimated, despite any efforts that may be made to prevent it. Indeed, there is very good reason for believing that the practice is increasing rapidly, and that many of us will see the consumption of them more than doubled. Whenever the discovery of remedies like chloral, salicin, cocaine, or antipyrin is announced in medical journals, there shortly appear in the lists of trade-marks registered in the United States Patent Office, the titles of nostrums containing one or another of these new agents as ingredients, and, coincidently, the columns of secular and religious papers, agricultural magazines, and board-fences take on a new coat of gorgeous colors, rhetorical and otherwise, proclaiming the virtues of these remedies for the various conditions which have been reported in medical journals as capable of being relieved by them. Indeed, few physicians read the current medical journals with closer attention to business possibilities than do some of the leading nostrum makers. This aspect of the question is, unfortunately, without remedy, since medical literature must be as available for one as for another, and physicians will continue to publish the results of their experience without regard to the possible uses to which it may be put. There is no reason, however, why the aid derived from the profession should extend further, nor that physicians should aid by patronage and recommendation to create a market for these wares, in place of articles equally or more desirable, and which can be manufactured and sold by any person who has the capital and skill that may be requisite.

Owing to a very general lack of knowledge among physicians of matters relating especially to pharmacy, it has been the aim of many manufacturing pharmacists to create a false impression of the amount of skill which is required to produce even the articles in so common use as those enumerated in the Pharmacopœia; and recognizing the fact that, in the case of our older and most used remedies, it will be impossible for them to control their sale by the adoption of a proprietary trade-mark, they spare no opportunity for impressing medical men with statements of their unusual facilities for manufacturing, the uniform and high character of their wares, and extremely unreliable character of other manufacturers, and especially of the retailing pharmacist. If one were to believe all that is said and hinted, it would appear that the manufacturers on a large scale monopolize the wisdom and honesty of the pharmaceutical profession, and that little is left for the retailing druggist. The physician is urged to insist upon having Brown's sugar-coated pills and Brown's only, and to distrust any effort on the part of the retailing pharmacist to convince him that his own, or Jones', or Robinson's, are just as good. And just so far as physicians are influenced in their practice by these sataements, do they contribute to aiding the sale and consumption of nostrums. It may be the case that, in some exceptional instances, certain pharmaceutical products are, for some reasons, preferable to others known by the same general name but manufactured by other persons; but it will be found that the differences upon which these excellences depend are not owing so much to superior skill as to the possession of patented processes or appliances, or processes which are kept as trade-secrets.

I would like, in the way of illustration, to speak of several instances which have come to my knowledge, in which otherwise reputable dealers and producers have attempted to control the sale of valuable medicinal substances, when the titles by which these articles are known have been common property. Two will suffice. A recent instance is that of an Eastern firm, who recognized the money to be made out of *lanoline*, provided they could induce physicians to prescribe it by another name, for which they hold a trade-mark. They therefore adopted the name *agnine*, and as such advertise it extensively in professional journals. If they were to advertise it as *lanoline*, they would be advertising the business of every other drug-jobbing house in the world, and the more they attracted the attention of doctors to the remedial virtues of this substance, the more they would help their business competitors, because there is, so far as I am aware, no patent or trade-mark right connected with *lanoline* as a title or as a substance. Therefore, it became necessary at the outset, to insure that they should get the benefit of their own advertising, that they should own some other name, and induce physicians to prescribe it by *that* name and not as *lanoline*; hence we have *angine*.

Some years since an enterprising firm of Western druggists, who devoted a great deal of attention to pushing newly discovered remedies, found, with the aid of an agent on the other side of the Rocky Mountains, an article which had a reputation in the locality where it grew as an efficient cathartic. With a keen sense of business possibilities, they were careful to suppress all reference to the true botanical name of the drug, and, so far as possible, allowed only such preparations of it to come into the market as would give no clew to its source. The remedy proved to be unusually valuable, and the ingenuity of physicians and pharmacists was enlisted in solving the problem as to its true nature. So matters went on for a time—the name by which it was known, like most common names of plants, giving little or no clew to its origin, since the same name is often applied to very different plants and to a very considerable number of them—until one day someone, interested in the subject, got hold of enough of the original plant to serve for its identification by a botanist, and then, in poker parlance, the game was called, and there was a row. The botanist was abused like a candidate for the Presidency, and his relatives had to take their share of the mud that flew from the neighborhood of the firm whose secret was divulged; but not for long, since the latter soon discovered that they were only making fun for outsiders, and gaining no credit for themselves. Since then other men have got their own supplies of the crude drug, and have no difficulty in supplying the market with products quite as satisfactory as the original.

To come more particularly to the subject of the use of proprietary articles by physicians themselves, it is difficult to understand the disposition shown by many men of repute in the profession, to make use of things of unknown or uncertain composition. In the case of antipyrin, the process for the manufacture of which, although patented, is well known, it is somewhat different. Like antipyrin, there are now a number of articles, used as medicine, of great value, and to be deprived of them would be a great misfortune; but in every case the accurate composition of these substances is not a secret, and any chemist who chooses to do so can make them as curiosities, but not for sale or use. Our pharmacopœias give directions for establishing their purity, and none of them possess the objectionable features characteristic of the articles usually protected by trade-mark registration, since the latter rarely have any definite chemical or microscopical composition by which they may be identified, and can only be judged of by their crude appearances; usually the character of the label on the package containing them, slight as it may be, is the only guarantee of the nature of the contents. Therefore, I repeat, it is difficult to understand how it is that physicians are willing to use such things or encourage their use by others. That many physicians do so must be the conviction of those who know anything of the daily experiences of a drug-store. It is only a few days since a pharmacist, without mentioning names, told me of a professor in one of the medical colleges of this city, who writes prescriptions for "Green's August Flower," instead of prescribing the officinal mixture of rhubarb and soda, which is practically the same thing, with this difference, that the latter can be made by any apothecary, while no one but the owner of the right to use the name "Green's August Flower" can make and sell the compound to which this name is attached. Again, the formula of the officinal mixture being published and well known, can be varied by the prescriber to suit the indications of the particular case. Nor is this all. When a physician writes a prescription for a Mixture of Rhubarb and Soda, the apothecary who dispenses under this name a mixture which does not meet the pharmacopœial requirements, does so at his peril; for the laws of this, and of all other States which have laws prohibiting the adulteration of foods and drugs, impose a penalty upon the pharmacist who tampers in any appreciable degree with the composition of remedies for which the Pharmacopœia of the United States of America furnishes a title and standard, while there is nothing but the maker's own sense of expediency which regulates the composition of a trade-mark article. The owner of the name "Green's August Flower" may thus make it of rhubarb, potash, and aloes to-day, and of senna and soda, and without the aloes, to-morrow, and so on, according to whatever drug may be cheapest or most available, or as his ideas of expediency may vary.

It is often argued that there are some old stand-bys, as they are called, or certain nostrums made by particular persons, which have been so long in use, or the makers of which are in such good repute, that there is little if any objection to their being approved or used by physicians; but I can appreciate no distinction, and, so far as professional recognition is concerned, there can be none. No physician can have any guarantee that the trade-mark article which he indorses to-day and which, perhaps, acquires a commercial value for its *title* largely through the indorsement which he and other doctors have given it, will continue indefinitely to justify in its nature the good opinion he had of it at the time his approval was expressed, and no man who appreciates his duty to himself, his profession, or to the public, will give a certificate of the value of something over which he has no control, and which in time may come to be vended on the strength of such certificate, without regard to the nature of the article itself. John Doe, to whom the certificate is given to-day, may be an honest man and worthy of confidence, but if to-morrow he should die, or should fail in business, the certificate becomes a part of his estate and falls into the possession of Richard Roe, who has quite a different character, and less scrupulous regard for the use to be made of this piece of property.

I wish that time permitted me to point a moral by a recital of a few instances in which professional indorsement, given in good faith, has discredited those who allowed their names to be so used, but I will only refer you to the history of Perkin's Tractors, and Swaim's Panacea of former times, or so-called Hungarian Wines, and hospitals for the cure of chronic diseases of our own day. Surely, if physicians appreciated the ways in which they exchange their birthright for a mess of pottage in lending their aid to making reputations for proprietary articles, there might be some fewer nostrums, and their skill as physicians would be greatly enhanced.

Do not be deceived by ingenious advertisements in medical journals, the statements accompanying physicians' samples, or that class of advertising circular so commonly announced as intended "for the Medical Profession only." It is true that references to the articles referred to are sometimes—indeed, too often—seen in monographs and journal articles, and that their labels or wrappers often profess to give formulas for their composition. You may be sure that the men who furnish the indorsements are either ignorant or indolent, and that the formulas are frauds.

The maker of nostrums, for all essential purposes, has no more skill and possesses no greater resources than the open manufacturer, and, much as he may boast of his regard for the good opinion of the profession, it is only the old story of the use the monkey made of the cat's paw to get his chestnuts safely out of the fire.

MEDICO-LEGAL NOTES.

By HENRY A. RILEY, Esq.,

NEW YORK.

Quite an interesting case in regard to undertakers has recently been tried in the city of Camden, N. J. In this case a person living next door to the undertaker endeavored to obtain an injunction against the further prosecution of the business, on the two grounds that it was so conducted as to be a nuisance, and in addition that the business was a nuisance *per se*, and should be abated, no matter how it was carried on. The case, therefore, presents many points of interest to every one living in a crowded city.

The facts showed that the defendant buried from one hundred to one hundred and fifty persons a year, and that the vehicles he used were driven to and fro from his residence about four times in each case, so that the complainant had the opportunity, if he paid attention to the matter, to be reminded from five hundred to six hundred times a year that a death had occurred, that some one was a corpse, and that preparations were being made for the funeral. In every such case the defendant used a large box, in which the corpse was preserved, as far as possible, from decomposition by use of ice in another box made of tin, which was placed directly over the corpse.

The boxes containing the corpse were taken, after they were used, into the defendant's backyard, and after being washed and dried were taken into the house again. The boxes remained out an hour or longer, and occasionally all night. The business seemed to be carried on as unobtrusively as possible, but these circumstances were relied on to secure an injunction. It is evident that if the court had held that the business was a nuisance, it would be difficult to carry it on anywhere in a crowded city, and probably more inconvenience would arise than could ever occur from having the signs of funereal woe frequently brought to a person's sight and attention. The decision of the court was against the plaintiff on both points involved, and in regard to the question whether the business was a nuisance *per se*, it said: "Must the undertaker retire from the inhabited parts of our villages, towns, and cities? Is an occupation, which is absolutely essential to the welfare of society, to be condemned by the courts, to be classified with nuisances, and to be expelled from localities where all other innocent and innoxious trades may be carried on? In other words, is this business so detestable in itself as unreasonably to interfere with the civil or property rights of those who dwell within ordinary limits, and who can and do without effort see and hear what is being done? The inquiry is not whether it is obnoxious to this or that individual or not; but, whether or not it is of such a character as to be obnoxious to mankind generally, similarly situated. There are certain obscure or offensive sights, certain poisonous or destroying gases or odors, certain disturbing sounds or noises, which affect most persons alike; can the business of an undertaker be classed with any of these? Is the business of an undertaker of this class? Before the court can condemn a trade or calling, it must appear that it cannot be carried on without working injury or hurt to another; and as I have said, that injury or hurt must be such as would affect all reasonable persons alike similarly situated. The law does not contemplate rules for the protection of every individual wish, or desire, or taste.

"It is not within the judicial scheme to make things pleasant or agreeable for all the citizens of the State."

The New York Legislature has before it a measure requiring the manufacturers of patent medicines to print on the labels a statement of the various ingredients used. This bill has aroused the wrath of the manufacturers, and they have argued before the Committee that the passage of the bill would utterly destroy a large and important business. The extent of the business has been shown by statistics, which prove that a large part of the population must be consumers of patent medicines. There are in New York State 108 manufactories, with a capital of $3,512,430, and a yearly output of $4,339,178. In the whole United States there are 563 manufactories, employing $10,620,880 capital, and sending out each year medicines of the value of $14,682,492.

Dr. R. V. Pierce, of Buffalo, one of the largest manufacturers, was the principal spokesman before the Committee against the bill. He said that it had been argued that proprietary medicines were harmful, but he had never heard a complaint, and he challenged anyone to show that these medicines had ever killed or harmed anyone. He said it would be preposterous to print the names of the drugs used on the labels of the bottles, and that it would be unprecedented to give into the hands of the State Boards of Health the right to require this to be done. If a board of health consisted of allopaths, they would say that homœopathic medicines were useless, and prevent their being sold. In Dr. Pierce's opinion the bill, instead of being intended merely to protect the public by preventing harmful drugs being used in medicines, was only an effort to absolutely destroy the whole business. He urged the Committee not to strike such a blow, and render valueless an immense amount of capital. The further progress of the bill will be observed with interest.

In a recent Ohio case the strict liability of apothecaries for mistakes in putting up prescriptions was again declared. In this instance it appeared that an Italian, quite ignorant of English, asked the druggist for oil of sweet almonds, a drug desired by his wife in her confinement, and frequently used by her previously. In place of the oil of sweet almonds, the druggist's clerk put up, by mistake, in the bottle the oil of bitter almonds, and did not indicate in any way that it contained a poison. The patient swallowed the contents of the bottle and almost immediately died. In a suit for damages the druggist denied his liability for his clerk's mistakes, and the case was very vigorously defended. The jury brought in a verdict against him for $1,000—a very small amount under the circumstances—and this decision has now been affirmed on appeal. One of the points claimed by the defendant was that he could not be held liable unless it was shown that the Italian was the agent of his wife in purchasing the drug. This sophistical objection was brushed away by the Court, which said: "It is not a sound proposition to say that a dealer in drugs, having in his stock and for sale deadly poisons, owes no duty to persons who do not deal directly with him in relation to them. The public safety and security against the fatal consequences of negligence in keeping, handling, and disposing of such dangerous drugs is a consideration to which no dealer can safely close his eyes. An imperative social duty requires of him that he use such precautions as are likely to prevent death or serious injury to those who may in the ordinary course of events be exposed to the dangers incident to the traffic in poisonous drugs. The jury found that Foster, the agent of the defendant, sold a deadly poison to a customer without knowing it was a poison, and without ascertaining for what use or for whom it was purchased.

The Electrical Execution bill has just passed the Assembly in this State by a vote of 87 to 8, which is practically unanimous. This is the natural result of the recommendation made by the Commission appointed to consider the whole question of capital punishment. The Senate is expected to be as favorable to the proposed method as the Assembly has been. It is noticeable that civilized countries use widely different forms of the death penalty. Out of 37 European states, including the 19 cantons of Switzerland, 10 make use of the guillotine; 19 the sword; 3 the gallows; 2 the gun; 1 the garrote; and 1 beheads with the axe. If the Legislature should, in addition to the proposed law, pass another requiring executions to be less public than they are, it would be a considerable gain for public order. The last execution in this city was public enough to allow of a shameful exhibition of newspaper enterprise. Comparatively few persons were admitted to the Tombs yard, but the position of the gallows could be seen from neighboring buildings, and one of the principal newspapers in the city had its reporters placed so that by waving a handkerchief at the precise moment the drop fell, the motion was seen at the window in the newspaper office, and the fact of the execution was instantly printed. Hundreds of "extras" were in a few moments being shouted through the streets, and the proprietors were enabled in heavy head-lines and with the consciousness of a great feat accomplished, to announce that they were five minutes ahead of every rival.

The battle over oleomargarine still goes on. The Massachusetts Health Board has recently decided that the compound is a healthful one, and the public should be permitted to have it. This, however, is largely the position of persons in other States, only they wish the public to have it under its own proper name and not as genuine butter. The dealers in the article evince a most decided objection to this proposal, and evidently are able to find few purchasers when the article is labelled oleomargarine. In Pennsylvania the Supreme Court has recently declared constitutional a law prohibiting the sale of the compound. In this State comparatively little seems to be offered for sale under its own proper title, and the supervision is so effective that not very much is sold as genuine butter.

The effort to prevent persons from practising medicine in this city, until the requirements of the law have been carried out, is progressing vigorously, and one of the most recent instances is that of Dr. John Frederick Augustus Clausnitzer Adams, *alias* John Frederick Augustus Adams Clausnitzer, who was charged with practising as a physician under different names.

The Albuminates in Medicine.—The albuminates are a class of medicine which is coming into extended use. and one of the most highly spoken of, in therapeutical value, of the preparations of iron, is that which falls into this category. In Germany albuminate of iron has already been successfully introduced into medical practice. and will doubtless sooner or later be put upon its trial in this country also. The following formula at present is found to be the most suitable. Of dried egg-albumen 2.5 parts are dissolved in 30 parts (all, including the following, by weight), of cinnamon-water, forming solution No 1. Then 12 parts of liquor ferri perchloridi are diluted with 40 of water and 12 of spirit, forming solution No 2. These two are then mixed together, shaken, and half a part each of liquor ammonia and liquor soda immediately added. The whole is thoroughly agitated until completely mixed. The product is a reddish-brown, somewhat oleaginous-looking liquid, with a sweet taste and a slight alkaline reaction. It is miscible with all proportions of water, and with milk, or other albumen-rich fluids, without precipitation. The former liquid forms a suitable vehicle for its administration, and the dose is from one to four teaspoonfuls several times a day. Prolonged boiling will not separate the albumen of the preparation.—*Lon. Cor. Journal Amer. Med. Assn.*

Clinical Department.

THE PASSAGE OF A HAIR INTO STENO'S DUCT, CAUSING AN EXTERNAL ABSCESS AND FISTULA—OBSERVATIONS OF THE PAROTID SECRETION.

By S. W. Overall, M.D.,

Memphis, Tenn.

On December 6, 1887, while at dinner, and eating a piece of barbecued pig, I discovered a stiff hair, about an inch long, in my mouth, which I supposed was either from my mustache or a pig's hair.

On attempting to push it out with my tongue, it became engaged in the right side of my mouth. Further efforts to dislodge it with my tongue evidenced the fact, by its becoming shorter, that it was entering my jaw. It then occurred to me that it was being forced into Steno's duct. I tried immediately to extract it with my fingers, when it disappeared. I arose from the table and went into Dr. J. L. Minor's office, and related the above facts to him. He made a careful inspection, but could see no signs of the hair, and advised me to await developments, which I considered the best course.

I experienced but little trouble for three or four days thereafter, except a general soreness on the right side of my face. At the expiration of two weeks, a small tumor began to form at about the middle of the duct and in the muscles. It continued to develop slowly, externally, for three weeks, with but little tenderness and no sign of suppurating. To favor suppuration I began kneading it, when the inflammation extended to the parotid gland, which became very painful. On the subsidence of the inflammation I detected pus in the tumor, and had Dr. Minor cut down upon it, when about a drachm of pus escaped; but, although he probed and seached for the hair for some time, he could not find it. A tampon was inserted to keep the wound patulous, and favor suppuration and exit of the hair. Not until then did my annoyance begin. At my first meal after the operation saliva forced the tampon out, and began running down over my face, and so freely at times that it would saturate a large handkerchief.

For six weeks the wound remained patulous, discharging only a few drops of pus daily, with no signs of the hair nor indications of healing.

During this entire time saliva flowed freely through the fistula, although I made several unsuccessful efforts to prevent it with tampons and compresses.

Members of the profession with whom I consulted at different times advised waiting, saying that if there was a hair there it would come out through the opening. I began to fear permanent fistula, or serious results to the parotid gland should the hair pass into the gland, so on February 14th last, Drs. J. E. Block and F. A. Moody operated by making an incision, an inch long and as deep into the muscles as practicable, using cocaine as an anæsthetic. I urged them to continue their search for the hair, which they did for three-quarters of an hour, but could not find it. A tampon was left in the wound, as in the first operation, to favor suppuration, etc. I was very much discouraged, although about the third or fourth day after the operation the wound seemed more inclined to heal than it had at any time previously, though the saliva continued to pass through it. On the morning of the 22d (seven days after the operation), while dressing the wound, I discovered something sticking out of it, and, on slight pressure, out came the hair doubled upon itself. The hair was an inch long, and very much disorganized and fragile. The wound closed in a few days, and I have had no further trouble with it. It left a considerable scar.

As I once occupied the Chair of Physiology in a medical college for five years, I was very much interested at first in studying the effects of different stimulants to the parotid glands. My observations were briefly as follows:

Movements of the lower maxillary had no appreciable effect upon the gland. Acids, introduced into the mouth without movements of the jaw, would invariably cause a free flow of saliva. Mastication, with acid ingestion, would cause the greatest flow. I do not believe the movements of the jaw alone had any effect in exciting the flow of saliva, but the process of mastication diffused the acid in the mouth over a greater surface. Citric and acetic acids were most active. Food free from acids would produce very slight flow.

A CASE OF RECURRENT MACULAR SYPHILIDE.

By T. H. ROCKWELL, M.D.,
HOUSE PHYSICIAN, CHARITY HOSPITAL, NEW YORK.

On account of the extreme regularity with which the early symptoms of syphilis present themselves, it is interesting to the profession to note any deviations from the usual order of events. Perhaps the most constant symptom after the initial lesion is the development, in from four to eight weeks, of the syphilitic roseola. The course, duration, and time of appearance of this eruption is not the same in all cases, for it may be influenced by the food, drink, moral habits, and physical condition of the patient, and when treatment is early begun it may greatly modify the character of the eruption; but never, according to the commonly accepted theory, does it entirely prevent its occurrence, although the erythema may be so slight as to be barely perceptible, especially by the patient. The roseola ordinarily appears but once in the history of the case, although relapses may occur, but in this event the eruption usually coexists with a papular or vesicular syphilide, and there generally remain some traces of the previous erythema.

Cases in which a macular syphilide occurs several months after a previous similar eruption are very rare, and their existence has even been denied by some authors. The following case, therefore, possesses considerable interest:

M. K——, aged thirty-three, was admitted to Charity Hospital in May, 1887, and had at that time a venereal sore, which had nearly healed, on the upper part of the right labium majūs. This sore was first developed about the middle of April, and had previously been treated as a chancroid, but there was a slight amount of induration about it when she entered the hospital. There was also a vulvo-vaginal abscess of the right labium, which was opened, and a small quantity of pus was evacuated. The abscess was dressed with iodoform, and healed kindly.

During the second week in May there appeared a well-marked macular eruption, bright red in color, the spots being from one-fourth to one-half an inch in diameter, extending over the entire body, commencing first on the abdomen and thorax, and extending thence to the extremities.

Coexisting with the roseola was an intense iritis of both eyes, also marked alopecia, inguinal, epitrochlear, and cervical glandular enlargement. There were rheumatic pains about the joints, and mucous patches were discovered in the mouth. There was but slight laryngitis.

The pill of the protoiodide of mercury, two-fifths of a grain, was given three times daily, and a solution of atropine instilled into each eye.

Soon after commencing this treatment she improved rapidly, and finally the symptoms disappeared, except the glandular enlargement, which, although reduced in size, could still be felt. The eruption faded, leaving slightly pigmented spots in the skin. As all visible manifestations of the disease were gone, the patient left the hospital in the latter part of June.

On March 3, 1888, after a debauch of three days, nearly ten months after the roseola first appeared, she noticed a well-marked eruption on her body. While absent from the hospital she had taken no medicine at all, except an occasional dose of Epsom salts, nor had she become overheated, and the undergarments were of old white flannel, not irritating to the skin. As soon as the eruption was discovered she came at once to the hospital, where an extensive macular syphilide was found over the entire body except the face. The spots were of a pale red color, level with the surrounding surface, disappearing on pressure, and accompanied by no pruritus. The skin had shown no papules, squamæ, or vesicles, the well-marked macular eruption being the only local manifestation. Soon after the appearance of the eruption, the alopecia, which had at one time nearly ceased, began to be quite marked, and rheumatic pains in the joints were developed. Her general condition was good, there being no constitutional disturbance at the time the eruption was developed. She was put upon a mixed treatment of the biniodide of mercury and potassium iodide, which caused the eruption to fade away, so that three weeks later there remained only a coppery stain on the surface of the skin. With the exception of these two macular eruptions, the patient has never had any cutaneous manifestations of syphilis, although the time for the papular eruption to commonly appear had long passed before the second macular syphilide was developed; nor was she at that time receiving any treatment which would retard the production of the papular eruption.

A recent writer has made the statement that "the phenomena of syphilis are most regular in their occurrence." Ordinarily they are, but the above illustration shows an exception to the rule, and proves, moreover, that it is possible to have an early lesion appear much later in the disease than is usually the case.

LOCAL APPLICATIONS OF CARBOLIC ACID IN CARBUNCLES.

Dr. James McManus, of Brooklyn, writes: "Apropos of the letter of Dr. Carleton, of Lawrence, Mass., in The Medical Record, of March 17th, I would like to mention the following circumstance: While assistant physician at the Hospital for Incurables (Insane Asylum), Flatbush, L. I., in the winter of 1882–83, I was called by one of the nurses to see a patient in the female wards. I found her with a large carbuncle on her left thigh. The patient had probably been suffering with it for several days before my attention was drawn to it; and, when examined, the carbuncle had a very unhealthy appearance, and the patient was to all appearances very sick—so sick that I fully expected her death. I had been preparing carbolic-acid solutions in the drug-room that morning, and scarcely knowing what to do—believing, as I did, that nothing I could do was of any use—I sent what I thought was a five per cent. solution of carbolic acid to be used as a wash. On visiting her again in the evening I was surprised to find my insane patient very much better in appearance, and was still more so to see that the carbuncular swelling had decreased to one-third its former size, and in place of the almost gangrenous appearance of the morning, had assumed a vastly more healthy appearance. I had given ten-minim doses of tr. ferri chlor., but as she had only taken two doses of that, I could not attribute the changed appearance to the action of the drug. On examining the wash I found that, by mistake, I had given a fifty per cent. solution of carbolic acid, which the nurse had faithfully applied by wetting a cloth in it and placing it over the carbuncular swelling. I kept the fifty per cent. solution on the patient that night, but substituted a weaker one the next day. In a few days the patient was entirely well. I have always believed that that mistake of mine saved that miserable, incurably insane patient's life."

German Drug Stores are apparently rather less trustworthy than American or English, if one may judge from recent revelations. A Berlin Society sent out a long series of bogus prescriptions, containing, for example, "tuber cinereum," "urticaria rubra," "pempuygus foliaceus." These things were dispensed and paid for in over sixty Berlin drug stores.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, May 12, 1888.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

THE meeting of the American Medical Association, a telegraphic report of which we publish in our present issue, may be considered to be a success from several points of view. The attendance was reasonably large, the subjects discussed were of an interesting and practical nature, and the addresses were in keeping with the dignity of the occasion.

The worthy President, in a direct and forcible manner, referred to the present defects in our methods of education, and the necessities for increasing the standard of requirements and of reducing the number of medical schools. Everything he said is absolutely true and cannot be told too often. If there is any important missionary work that the American Medical Association can do, it is certainly in the direction suggested by the clear-headed and conscientiously outspoken orator.

It is still a question, in view of the interested opposition of the medical schools, whether or not any good can be accomplished in the direction suggested. THE MEDICAL RECORD for many years has advocated reform, but the schools as yet have had things their own way. No argument worthy of consideration has been offered against independent State examining boards. Every time the question comes up before a State legislature, the Medical Colleges are on hand to oppose it by every influence in their power. The reason is apparent. These schools cannot afford, as purely business enterprises, to run the risk of such an impartial supervision of their work as would necessarily curtail their licensing privileges.

To sit in judgment upon the methods of many of these schools would mean ruin to the stockholders and self-constituted professors. But the end must come, sooner or later, and to the courageous criticism of the worthy President every medical man who is not specially interested in the pecuniary prosperity of some college will heartily say "Amen." We say, in the name of the profession at large, let us call a halt along the line. Slacken the speed of the mills and give us a better opportunity for examining and sorting the grist. The profession is now crowded to overflowing. There is a glut in the market which is appalling, and yet "the cry is still they come."

The addresses delivered during the session were listened to with deserved attention, and were models of their sort. The reports made were also well digested and to the point. At the risk of invidious comparison, the one on dietetics was of great importance, and set forth in a very clear and common-sense way the true philosophy of the art of feeding. No better rules have ever been formulated regarding this question than those bearing on infant diet, and it is a matter for congratulation that the associated press of the country has so widely disseminated the sound doctrine, and placed it within the reach of every mother in the land. It is such reports as these that tend to place legitimate medicine on its properly dignified basis before the world.

The meeting, besides, was a harmonious one. No differences of opinion on ethical questions were ventilated, and a spirit of more than ordinary liberality and charitableness prevailed. This was as it should be, and is a proper beginning of an end which all good men earnestly hope for.

THE FUNCTION OF THE THYROID GLAND.

MUCH interest has been excited on the subject of the function of the thyroid gland, especially since it has been shown that serious constitutional changes follow its removal. These changes, as our readers know, have been observed in monkeys in which the gland was removed experimentally, and in man when the gland was destroyed by disease. Animals or men deprived of the thyroid gland develop an apathetic mental state, ending, finally, in almost complete imbecility. They suffer from tremors, sometimes from convulsions, and often have a subnormal temperature. A peculiar infiltration of the subcutaneous tissue with a myxomatous material takes place. The condition has been described by surgeons as cachexia struma priva, and it closely resembles the disease known as myxœdema, in which the thyroid appears to be atrophied.

At a meeting of the Munich Medical Society, on January 11th, an interesting debate took place regarding the function of the thyroid gland, and, in particular, as to its relation to the nerve-nutrition of the nervous system.

Professor Ruedinger held that it was impossible to attribute the peculiar effect of thyroid extirpation to any mechanical action which that gland might have upon the intracranial circulation. The fact that the brain may be normally nourished, even where both carotids and one vertebral have been obliterated, seems almost conclusive evidence in this direction. It is held, therefore, that we must fall back upon a chemical theory to explain the consequences of its removal. The view that the thyroid, like certain other blood-glands, elaborates a material necessary for the proper composition of the blood, is the one that must be usually adopted. Horsley found seven per cent. more white blood-cells in the venous blood of the thyroid than in the arterial. Most of the speakers, in the discussion referred to, inclined to this chemical view of the question. Professor Bollinger, however, doubted if so small an organ could have so important a function, and Professor von Liemssen reported a case in which this gland had been totally destroyed by sarcomatous disease without any resulting influence upon the nervous system.

We must, for our part, express a very decided adherence to the chemical or glandular theory of the function of the thyroid. It is a gland somewhat of the order of the suprarenals, *i.e.*, it has as its function, no doubt, the destruction or further elaboration of nitrogeneous metabolites.

When destroyed or removed these partially disintegrated products enter the general system and poison it; as with the supra-renals, this condition may not always follow its disease, since other blood-glands may assume its function. But that it is a powerful auxiliary in retrograde metamorphosis there seems, in the light of present knowledge, but little doubt.

THE STUDY OF ANATOMY.

THE last edition of "Gray's Anatomy" (the eleventh) has been before the medical public for some months. The journalistic notices it has received have been uniformly favorable and in some cases extravagant. The American edition, under the able supervision of Dr. Keen, is in some respects better than the English. In this country, "Gray's Anatomy" is generally the first book purchased by the medical student, and it speedily becomes the bane of his existence.

In looking over the kindly criticisms alluded to above, we are struck with the appearance of an idea rather new to book-notices. In some journals the new idea stands boldly forth; in others it has hardly dared to lift its head. But it is there all the same, and may be characterized as a tendency to break loose from the old ideas concerning the proper methods of teaching and learning anatomy.

This foundation study of medical science is to its votaries very much what geography is to the pupils of the common schools. Until very recently the method of studying the latter branch has been purely a mnemonic one, entirely devoid of any appeal to the higher intellectual faculties of the scholar. Description has been entirely divided from analysis, and the rising generation has crammed its head full of the names of rivers, counties, and towns, with a very indefinite idea of their mutual situations and relations.

But prominent educators finally saw that this was beginning at the wrong end, and they conceived the plan of map-drawing and map-constructing. The project was from the first successful, and from that time the study of geography has been pursued with relish, even by young children.

A criticism in the same line may be made on the current methods of studying and teaching anatomy. It is a fault common to all books and all schools. Of the new Gray, one critic says that it is sadly deficient in this, "that the student is not given an introduction as to the relations of the science of anatomy to other sciences, especially to morphology and biology. . . . It is an undeniable fact that the genetic method of explaining anatomical facts illuminates the process of teaching and learning, and thus not only the memory, but the reasoning powers of the student are exercised. The time has come when the old mnemonic method of learning anatomy can no longer be tolerated. 'To teach means to develop.' Therefore, there can be no doubt that the genetic method should always work hand in hand with the descriptive.

"It seems to us, that at the present time a physician should be more than merely a practitioner of medicine. He should be instructed in the scientific foundations of the disciplines which he needs in the practice of his profession. Lacking these, he is little better than an artisan, and will never be able to reach the noblest aims of his profession."

This criticism contains in general terms the new idea. The division of anatomical study into bones, ligaments, muscles. etc., while well enough in its way, makes the study a too disjointed one to arouse any enthusiasm among students. The satisfaction of dissecting-room work comes largely from the fact that the relation of parts is apparent at a glance. The lectures on regional anatomy are always the most popular ones of the year, and for a similar reason. Furthermore, the proper methods of study being thus taught at the commencement of a medical course, the effect is manifest in the acquirements of succeeding years. We can well imagine many a man has felt discouraged as he has tried to remember all the foramina-angles and corners of some of the bones of the skull; and when, in after years, he has come to realize the practical worthlessness of much of this kind of knowledge, his feeling is one of disgust at the recollection of so much wasted energy.

To teach anatomy as it should be taught will relegate much of the didactic teaching of the present day into the background. Greater laboratory facilities will be required, and more systematic work in dissection. But it is the foundation study of medicine and surgery. The more thoroughly it is studied, the better the superstructure that can be placed upon it.

POSTURE AND RECTAL DISORDERS.

THE study of the posture of the human body in its relation to the needs of daily life has received a new impetus from Minneapolis. A physician of that city contributes to the *Northwestern Lancet* an article demonstrating that the squatting posture is the natural and proper one in defecation, and that the adoption of it tends to relieve constipation, heal hemorrhoids, and prevent uterine displacements. This physiological squat, it is believed, places the body in a position adapted to secure the greatest pressure on the abdominal walls and rectum. Besides this, it is so uncomfortable that the operator has to attend strictly to the business of the moment. He cannot dally with the morning paper while exposing the gluteal regions to subterranean draughts, and thus laying the foundation for fissures, piles, and prolapsus.

The squatting position is naturally assumed, says Dr. Abbott, by monkeys, apes, and man. In savagery and on the frontiers of civilization this posture is the ordinary one. But man seems to be a luxurious animal, and our writer must admit that, on the very first opportunity, he abandoned the ape position for any appliance that will support the thighs, from the edge of a board to the elegant ease of artistically perforated and polished mahogany.

Dr. Abbott apparently makes a strong point for the squatting posture when he says it is the one recognized by Holy Writ. While this may be the case, there is some reason, on the other hand, to believe that the squat is the natural position of the devil. At least we are told in "Paradise Lost," that

> "Him there they found,
> Squat like a toad close at the ear of Eve."

Hence it will not strengthen the case to bring in the religious factor. But Dr. Abbott puts the case most strongly when he pictures the indolence which the American temperament exhibits in the water-closet—the only place where he is not in a hurry.

"How far from nature," he says, "is the woman, who, perhaps intensely interested in the question of blue or green for her bonnet, will sit in deep contemplation for ten minutes, straining, between thoughts, as if in childbirth, finally concludes she was mistaken and goes back to the bonnet, to return to the closet again only after three or four days of constipation have given her a splitting sick-headache. Man abuses his blessed privileges in the same way, figuring perhaps on a real-estate deal instead of a bonnet, or perhaps with magazine in hand making increment above, but failing in excrement below."

If the primeval posture suggested will make men and women distribute the time devoted to their emunctories more judiciously, it may be a wise measure to adopt, although we fear that it is not destined to have a fair trial in any but strictly rural districts.

News of the Week.

Hudson River State Hospital, Poughkeepsie, N. Y.—Governor Hill has appointed Dr. George F. Shrady manager of this hospital in place of Dr. C. R. Agnew, deceased.

Commencement of the College of Physicians and Surgeons.—The annual commencement exercises of the College of Physicians and Surgeons were held last evening in the lecture-room of the College, Fifty-ninth Street and Tenth Avenue. Dr. Dalton, the President of the College, delivered an address on the progress of surgery, and Dr. Curtis then awarded the prizes offered by Dr. Harsen. The clinical prizes of $150 and $75 were won by H. L. Shively and H. W. Cardwell. The ten honor men were R. A. Sands, G. L. Nicholas, L. O. Wiggins, H. L. Shively, G. R. Hill, W. K. Draper, G. B. Cowell, A. Lambert, S. L. Weber, and G. B. McAuliffe. The honor prizes, which can only be competed for by the honor men, were awarded as follows: R. A. Sands, $500; Alexander Lambert, $300; L. O. Wiggins, $200.

Mr. Matthew Arnold had disease of both mitral and aortic valves. The affection was apparently hereditary. His father, Dr. Arnold, and two of Matthew Arnold's sons, succumbed to chronic heart disease.

The Female Physicians of Russia recently celebrated the tenth anniversary of their professional existence, by a banquet.

The Fifth Annual Meeting of the Conference of State Boards of Health was held at the Grand Hotel, Cincinnati, on Friday, May 4th, preceding the Annual Meeting of the American Medical Association.

The Medical Profession of Switzerland is urging the enforcement of the law withholding a license from any but graduates of the Swiss medical colleges.

Dr. Joseph Holt having resigned his position as president of the Louisiana State Board of Health, and removed from the State, Dr. C. P. Wilkinson, a graduate of the Washington-Lee University and of the Louisiana Medical University, has been elected in his stead.

A Young Medical Student of this city has been arrested on suspicion of having been concerned in the murder of Lilla Hoyle, of Webster, Mass.

Phenacetine.—Dr. Robert Bell calls attention, in the *British Medical Journal*, to a new antipyretic and antineuralgic agent, called "phenacetine," though, correctly speaking, it bears the chemical name of para-acetphenetidin, the formula of which is $C_6H_4 \left\{ \begin{matrix} O.C_2H_5 \\ NH(CO-CH_3). \end{matrix} \right.$ It can be given with perfect safety in doses of from eight to twelve grains every four hours. Phenacetine is a febrifuge which compares favorably with any of the modern antipyretics in the certainty of its effects and freedom from evil consequences. In fevers its administration is followed by relief of the symptoms; and in sciatica, "its utility cannot be overrated." Phenacetine is a white, crystalline powder, soluble with difficulty in water, but easily so in hot alcohol.

Total Removal of the Bladder.—It is highly probable that the bladder is the next viscus which will be successfully extirpated by the surgeon. The bladder is an organ of convenience rather than necessity, and it is better to be without it than to have it with a cancer developed upon its walls. The operation of total removal has been experimentally attempted upon dogs, but with the conclusion that such total removal, with proper diverting of the ureters, is very difficult, if not entirely impossible. Messrs. Ballance and Edmunds, however, have devised an operation ("St. Thomas' Hospital Reports," vol. xvi.) which it is believed will prove efficient.

Reciprocity in Medical Practice.—In the House of Parliament, on April 9, 1888, the following discussion occurred:

"Mr. Arnold Morley asked whether registered medical practitioners in the United Kingdom were afforded privileges of practising in the United States of America, and whether any steps have been taken or were in contemplation by the Privy Council, under section 17 of 'The Medical Act, 1886,' in the direction of similar privileges being given to legally qualified American practitioners who might be desirous of practising medicine in the United Kingdom."

"Sir W. Hart-Dyke replied that no statement had been received from the Government of the United States showing the privileges afforded in America to registered medical practitioners of the United Kingdom, nor did he find that any request had been made by the United States Government for the extension of privileges to American medical men in this country."

Dr. William B. Meany, of Chicago, who is at present in London, has written to an official representative of the United States in reference to the above point, as follows:

"I beg, sir, to state that registered medical practitioners of the United Kingdom are afforded all rights and privileges of practising medicine in the United States, on equal footing with graduates of medical schools in the United States of America.

"The same courtesy is shown members of the learned profession holding certificates of their qualifications from the United Kingdom, that is shown to residents of Sister States of America, under the same circumstances.

"We beg, sir, most respectfully to ask your aid and consideration for the purpose of having granted to legally qualified practitioners of medicine in the United States, the same privileges for those who may desire to practise medicine in the United Kingdom."

Society Reports.

American Medical Association.

THIRTY-NINTH ANNUAL MEETING,

Held in Cincinnati, O., May 8, 9, 10, and 11, 1888.

[By Telegraph to The Medical Record.]

Tuesday, May 8th—First Day—General Session.

The meeting was called to order by Dr. W. W. Dawson, Chairman of the Committee of Arrangements, in the spacious Music Hall on Elm Street.

THE PRAYER

was delivered by the Rev. R. A. Gibson, Rector of Christ's Episcopal Church.

THE VICE-PRESIDENTS,

Drs. Duncan Eve, Darwin Colvin, C. J. O'Hagan, and A. Stedman, were invited to seats on the stage.

AN ADDRESS OF WELCOME

was then made by the Mayor, the Hon. Amos Smith. Upon him, as chief magistrate of the city, devolved the pleasant duty of extending to the members of the American Medical Association a most cordial welcome from the citizens of Cincinnati; and he believed that this welcome would be of such a practical nature that any words of his were superfluous. No member should be allowed to leave the city feeling that he was a stranger. Since entering the hall he had been told of an order of a former mayor of Cincinnati, when the city was before honored by the meeting of this Association, twenty-five years ago. The police had been notified at that time that, should they hear laughter or noise on the streets at an unusual hour of the night, they might be conveniently deaf, for they would know that it was caused by some of those

ROLLICKING DOCTORS

on their way home. The speaker did not feel called upon to repeat his predecessor's order, yet he desired to offer the entire freedom of the city to his hearers, and if some of the younger members should happen to stay out a little late some night, the members of the Association might be assured that they would have no cause to complain of the treatment which these joyous young men would receive.

The power of acquiring scientific knowledge will be limited only by the last second of recorded time, and as surely as the rising sun foretells the glory of the coming day, so this meeting foretells great good to humanity. The Association,

BORN ON THE EASTERN BORDER,

now tempers socially and intellectually, with its offspring, all the population of the land.

In closing, the speaker said that this was the

CENTENNIAL YEAR

of the settlement of the Ohio Valley, and on July 4th would be opened the exhibition to commemorate this event. He hoped that his hearers would pardon him for calling their attention to this secular event, but he did so in order to extend to the members present an invitation to come again two months hence, and he assured them of another welcome as hearty as that which he now extended to them.

Dr. C. G. Comegys then delivered the

WELCOMING ADDRESS

on the part of the medical profession of the city. This was the third time that the Association had held its meetings in Cincinnati, the previous occasions having been in 1850 and 1867, and the physicians of the city, as well as all the citizens, appreciated to the full the honor which had been thus three times conferred upon them. It was sad to feel that a majority of those who, on former times, had constituted the members of the Association were now no more, yet their spirit still lived in their successors.

As this was the year in which the citizens of the Ohio Valley were to recall the first settlement of the region one hundred years ago, it might be profitable to review the events of the

PIONEER AGE.

It was an heroic age and a glorious race, whose achievements were now to be commemorated, and those of the present day were celebrating the occurrences of a century ago with the aim, not only to recall with gratitude the deeds of those gone before, but to seek in the remembrance of them an incentive to emulate the courage, the toil, and the public virtue of those early pioneers.

The colony that descended the Ohio River in flatboats and planted in this spot the beginnings of a new civilization was small in numbers, but strong in virtue and in courage. The men were of no common mould, and they succeeded, after many vicissitudes, in establishing an outpost of civilization in the distant wilds. With the establishment of quiet, came the desire of perpetuating, for the benefit of posterity, the culture which those hardy pioneers had brought with them from the East. What was wanted for the accomplishment of this end was

AN INSTITUTION OF LEARNING,

and for the establishment of this was needed a master mind. Fortunately, the young colony had not long to wait, for at this time, in the wilds of Kentucky, was growing to manhood one who was to accomplish great things for Cincinnati. This man was

DANIEL DRAKE.

After studying medicine for a while in this city he journeyed to Philadelphia, where he had the privilege of receiving instruction from Rush, Physic, and Wistar. After his graduation he was associated with Dudley, Caldwell, and Richardson in establishing the

FIRST MEDICAL SCHOOL IN THE WEST,

at Lexington, Ky. But he loved the city of his adoption, and, after delivering two courses of lectures at Lexington, he returned to Cincinnati, where he soon obtained charters for the Cincinnati College, the Medical College of Ohio, and the Cincinnati Hospital. The crowning work of his life was, however, the systematic treatise on

THE DISEASES OF THE INTERIOR VALLEY OF NORTH AMERICA,

to the preparation of which he devoted twenty years of study and of travel throughout the vast valley of the Mississippi. This work will always remain a monument to the fame of Daniel Drake.

All the great works of Drake still live. The Cincinnati College is the largest law school in the Ohio Valley, and the Medical College of Ohio is flourishing and of vigorous growth.

A SPIRIT OF ORIGINAL RESEARCH

has always animated the profession in this city, and it is largely to the labors of this great man, performed in the early part of this century, that is to be attributed the existence of this spirit.

Dr. Comegys then referred to the peculiar

GEOLOGICAL FORMATION

of the soil upon which Cincinnati is built. If one ascends the hills surrounding the city he will see that they are made up of stratified sedimentary masses belonging to the lower

SILURIAN EPOCH.

Between the layers are to be found large quantities of marine shells, showing that all the country about was once the bottom of a great body of salt-water.

The programme of the proceedings for the entire session was then announced, after which DR. A. Y. P. GARNETT, of Washington, D. C., delivered the

PRESIDENT'S ADDRESS.

In casting about for a subject concrete in its nature and directly useful in its application, he had determined, he said, to submit for consideration a few practical reflections upon the

MISSION OF THE AMERICAN MEDICAL ASSOCIATION.

The paternal relation of this association to the medical profession of this country placed it under the gravest responsibilities. But a retrospect of the almost half-century of its existence showed no reason for discouragement, and, in fact, many reasons for congratulation. The members should not, however, consider that they had accomplished their mission until they had brought about a radical and thorough reform in the present system of medical education in the United States. They should make every endeavor to elevate the system of medical education in this country to a standard equal in dignity and attainment to that which obtains in Europe. The annual meetings of the Association must not be held solely for the purpose of scientific consideration supplemented by the pleasures of social intercourse.

Rapid progress has been made in this country, in some departments of medicine, during the last decade, yet we are still confronted by the fact that

OUR MEDICAL SCHOOLS REMAIN VERY NEARLY THE SAME.

True, this subject has been constantly discussed, but the question still remains: What can this Association do to further raise and promote a higher standard of medical education in the United States, to curtail the number of medical schools, and thereby gradually to restrict to a conservative limit the annual host of graduates turned loose upon the public? An explanation of the fact of the failure of this Association to effect an improvement in medical institutions may be found in the fact that a large proportion of those who now attend the meetings are directly or indirectly connected with medical institutions and are influenced thereby. While they have done much for this Association, they have not wielded the power which they possess to further the advance in medical education. We have medical colleges in this country unsurpassed by those in Europe in their essential appointments and facilities for education, yet we fall far behind the latter in the systems of study which we pursue. There is also a radical difference in the education of the mass of students of this country and of Europe. The European medical student is confronted at the very threshold by the rigid requirements of a fixed collegiate standard. He must have some educational capital or mental training to build upon before he can hope to master the complex and difficult work before him.

In this country the multitude of medical schools offering to the educated and the uneducated, by low fees and short terms of study, inducements to become doctors, together with the almost universal

DESIRE AMONG LABORERS TO BECOME DOCTORS,

has worked incalculable mischief. We have waited almost a half-century for the desired reform to be effected, but our expectations have not been realized. Many excuses have been brought forward, but there is no excuse which will free the medical schools of this country from the responsibility of the odious defects of our system of medical education. The ratio of professional men in the United States to the population exceeds that of any other country in the civilized world.

THE RATIO OF PRACTITIONERS OF MEDICINE TO THE POPULATION

of the United States at present is about one to every 580, and there is little danger that this ratio will be lessened. The supply will always equal the demand, in despite of all difficulties. Over a hundred years ago, when medical education was much more difficult to obtain than at present, Addison, in his *Spectator*, said: "If, in the third place, we look into the profession of physic, we shall find a most formidable body of men; the sight of them is enough to make a man serious, for we may lay it down as a maxim, that when a nation abounds in physicians it grows thin in people. This body of men in our own time may be described like the British army in Cæsar's time—some of them slay in chariots, and some on foot."

To facilitate the attainment of a

HIGHER MEDICAL EDUCATION,

the speaker offered the following propositions:

I. That a standing committee, to be called a

COMMITTEE ON LEGISLATION,

be appointed for each State, Territory, and the District of Columbia, to consist of five members of the medical profession in good standing, three of whom shall have no official connection with any medical school, whose duty it shall be to carry out, as far as possible, the following instructions:

First: That said committees, or a majority thereof, shall attend the sessions of their respective legislatures, or as often as their duties may require it, for the purpose of using all honorable means looking to the

REDUCTION OF THE NUMBER OF MEDICAL SCHOOLS

in the United States, and a consequent diminution in the number of medical graduates. As a practical measure to this end, they urge the passage of a law requiring that, in the future, charters for creating medical schools shall contain a clause requiring that a full term of four years' study be required before the granting of a diploma to any student, and that no student shall be matriculated who has not passed an oral and written examination in the ordinary branches of academic study. Further, that any college failing to show a greater number than fifty matriculates annually, for three consecutive years, shall forfeit its charter and be abolished.

Second: That these committees use all diligent effort to secure an ordinance creating a

BOARD OF MEDICAL EXAMINERS

in each State and Territory, which shall have no connection with any medical school, and which shall be required to examine all applicants for license to practise medicine in their respective States. Any person practising any branch of the healing art, without license granted by said board, shall be subject to the penalties as the law may provide. This committee should also be authorized by statute to nominate, to the governors of the State and Territory, competent and learned members of the medical profession to constitute said board of examiners.

Third: That the chairmen of said committees of five be required to submit, at each annual meeting of this Association, a report embracing a full statement of what has been accomplished by each.

II. That the faculties of the several medical schools within the limits of the United States be once more urgently requested to

CALL A CONVENTION

at some central point, for the purpose of consultation and the adoption of some more general and uniform system of medical education. That, in addition to a four years' term of study, the requirement of a preliminary education, including some

KNOWLEDGE OF THE CLASSICS,

shall be suggested. Any school or college which shall refuse to enter into such an arrangement shall be excluded from all connection with the American Medical Association, and its alumni shall not be recognized as members of the regular profession.

The speaker said that he was aware that these suggestions embraced some very radical, and seemingly impracticable, changes. If these seeds fell upon barren soil, he would at least enjoy the consciousness of having honestly, conscientiously, and fearlessly met the great and pressing issue of the day.

DR. GARNETT then referred to the

INTERNATIONAL MEDICAL CONGRESS

in the following words: "It is with no little satisfaction that I can here refer to the successful meeting of the ninth International Medical Congress, which took place at the capital of the United States in September last. To my lamented and distinguished predecessor as President of this Association,

THE LATE DR. AUSTIN FLINT,

belongs the credit of having suggested, at the meeting in 1884, that this Congress, through the authority of the American Medical Association, should be invited to hold its ninth meeting in the United States. Through the ability and diplomatic tact displayed by the gentlemen intrusted with the mission of conveying the invitation to the meeting of the Congress at Copenhagen, Washington City was selected as the place for the meeting of the ninth International Medical Congress.

Notwithstanding the defection of some of those who were identified with the movement at its inception, and who subsequently disassociated themselves from all connection with the Congress, we entertain no misgiving as to what the verdict of the medical world will be:

"EQUAL, IF NOT SUPERIOR, TO THE WORK OF ANY PRECEDING MEDICAL CONGRESS."

The speaker referred to the founding and naming of the city of Cincinnati, just one hundred years ago, by Dr. Arthur St. Clair.

Reference was also made to the mortifying position in which the Rush Monument Committee has been placed by he apparent

LACK OF INTEREST

and liberality on the part of the medical profession of the country.

He concluded the address by offering congratulations upon the proud and enduring position now occupied by the Association. It is to-day more powerful, more self-reliant, more progressive, and stronger in the affection of its members than at any former period of its existence.

A vote of thanks was offered to the President, and it was moved and carried that the address be referred to the Committee on Publication.

DR. LEWIS A. SAYRE was invited to take a seat upon the stage.

DR. N. S. DAVIS presented a petition from many members, that the various sections be allowed to hold sessions in the morning as well as in the afternoon. This request was granted.

Invitations were presented to the members of the Association to visit the Chamber of Commerce, the College of Music, and the Technical School.

Dr. N. S. Davis stated that the secretary of the

JUDICIAL COUNCIL

had been obliged to resign on account of ill-health, and though, happily, there was no work for the Council to perform, the members were requested to meet in order to preserve their organization and be able to act in case of necessity.

In the evening the members met in the parlors of the Burnett House in an informal reception.

WEDNESDAY, MAY 9th—SECOND DAY.

The general session was called to order by THE PRESIDENT at 10.30 A.M.

DR. ROBERTS BARTHOLOW, of Philadelphia, delivered the

ADDRESS ON GENERAL MEDICINE.

The last International Medical Congress was, in some respects, the most important one that has ever been held, especially in regard to preventive medicine. To an unprejudiced observer it would seem that its proceedings ought to have received some consideration from the public press. Yet such was not the case, and this is the usual

POSITION OF THE PRESS TOWARD THE MEDICAL PROFESSION.

Those organs of public opinion do not ordinarily regard medical organizations seriously, and they seldom notice matters of the utmost importance to the general welfare of the community which may be discussed at these meetings. A surprising amount of ignorance still exists in this latter part of the nineteenth century, and people still think that the therapeutic art is based on some 'ism or 'pathy. On the Continent of Europe

HOMŒOPATHY IS NEARLY EXTINCT,

but here it still lives, being held up by social influences and by misrepresentations on the part of its advocates. The statistics upon which these men rely to win converts are often made up out of whole cloth, as was done by a Dr. Somers, whose pretended official figures, showing the results of practice in the larger cities of this country, seem to prove that homœopathic methods of treatment are fifty or sixty per cent. more successful in curing disease than are those of legitimate medicine. In one of the large cities of the West circulars were widely distributed in which the claim, based upon these supposed official figures, was made that regular medicine would soon become extinct in this country. The speaker had taken pains to consult the proper authorities in regard to the sources of these alleged official figures, and had found that there were none, and that the statistics were pure fictions. No further argument was necessary to establish the falsity of a system which had to resort to such means to insure its success. The remedy for this, which regular medicine has to offer, is to improve its art.

THE SCIENCE OF THERAPEUTICS

should be made more certain. This is a branch of medical study which is not cultivated as it should be, and a true knowledge of drug-action is not widely enough diffused. The acquisition of this knowledge is greatly hindered by the mass of old prejudices which still cling to this science, and impede its progress like the barnacles on the hull of a ship. All this complexity and superfluity of olden times must be wiped away; at least two-thirds of the pharmacopœial preparations could be dispensed with, and scientific therapeutics would thereby be the gainer.

The knowledge of a drug and of its various constituents should be thorough, and only its active principles, or, if these have not been isolated, its strongest and most constant preparation, should be prescribed. In

THE ALKALOIDS

we have singleness and simplicity of action, and they may also be given in small doses and in a form most agreeable to the patient. This is a matter of no small importance.

The speaker then referred to the

DOSIMETRIC SYSTEM OF MEDICINE,

into the claims of which he had carefully examined, but which he did not consider as in any sense new. Furthermore, the system was crude, and its adherents did not usually base their modes of treatment on true scientific grounds.

A great objection to the employment of a crude drug was its uncertainty of action. In the case of

JABORANDI,

for example, there were two alkaloids, pilocarpine and jaborine, whose action was dissimilar, and in prescribing the crude drug the practitioner could not be as certain of obtaining the desired result as when an alkaloid was exhibited. Many other drugs, such as opium and nux vomica, offered examples of this same complexity of action. The study of

THE PHYSIOLOGICAL ACTION OF REMEDIES,

as a basis for their scientific use in the case of disease, is still young and dates only from the early part of this century. It is a curious fact that, at the same time that the foundations of our knowledge of the physiological action of remedies were being laid, Hahnemann and Mesmer were imagining the spiritual essence. An illustration of the utility of the modern methods of the study of therapeutics is furnished in the employment of the nitrites in the treatment of angina pectoris. It was through the knowledge of their physiological action, experimentally obtained, that they came to be employed therapeutically. Homœopathy, the speaker maintained, had nothing to do with the progress of modern scientific medicine. The true therapeutic action of drugs was one of antagonism.

Therapeutics also presses into its service the physical forces whose action is fixed and according to known laws. Even the most sceptical is forced to admit the

EFFECTS OF THE GALVANIC CURRENT UPON CONGESTION

and upon the products of inflammation, such as strictures. Electrolysis is comparatively new in its application, and it is full of therapeutic promise.

The address was referred to the Committee on Publication.

Dr. J. H. Hollister, Secretary of the Board, presented the

REPORT OF THE BOARD OF TRUSTEES ON THE PUBLICATION OF THE "JOURNAL,"

showing that it was in a flourishing condition.

Dr. Wood presented the

REPORT OF THE COMMITTEE ON DIETETICS.

He stated that this was intended to be only a preliminary report, and suggested that the original committee be enlarged, or that a section on dietetics be established. Thinking Americans, he said, are beginning to recognize the peril attending the use of bad food badly prepared. The young science of dietetics has joined hands with organic chemistry and with physiology. It has also taken the cook by the hand, and is raising the preparation of food to the dignity of a scientific pursuit. It has also entered the schools, and young girls are beginning to be proud of their ability to cook, and they now recognize that the humming of the tea-urn is sweeter music than the sound of the piano. Housewives are learning that a neatly laid table and a clean table-cloth are potent in keeping the men of the family from the grog-shop, and do more good for the cause of temperance than all the orations of professional lecturers. It is said that Americans are a race of dyspeptics, and this is partly true. But a dyspeptic race must inevitably deteriorate, and the physicians of the land, from motives of pure patriotism, if for no other reason, should put the axe to the root and seek to prevent it, by inculcating in the minds of the people

THE NECESSITY OF GOOD AND WELL-PREPARED FOOD.

But in the treatment of disease, as well as in its prevention, the science of dietetics has before it a great work. It is often more easy to lead the sick back to health by the food route than by the drug line, and it is a curious fact that he who relies least upon drugs has the greatest confidence in their action. Drugs often fail when relied upon exclusively, but may work wonders when combined with a proper diet. There is, however, one abuse which has crept into modern medicine, under the apparent sanction of dietetics, against which the committee desired to raise its voice in protest. That abuse was the

TOO GREAT RELIANCE OFTEN PLACED UPON VICARIOUS DIGESTION.

The giving of nourishment in other ways than by the mouth may often be necessary, but it has its limits of usefulness. It can never be of any but temporary service, for it supplies only a low grade of nutrition. If it is employed for too long a time, or when not absolutely necessary, it makes paupers of the digestive organs and unfits them for the proper discharge of their functions.

Dr. Woodbury then read the

REPORT OF THE SUB-COMMITTEE ON INFANT FEEDING.

The committee had had the subject under consideration for only a short time, and was not yet prepared to make a final report, but it would offer the following as useful facts: 1. In the case of infants deprived of breast-milk, the artificial substitute should correspond as nearly as possible to human milk. 2. Cow's milk corresponds to breast-milk in most respects, but its caseine should be broken up, so as not to coagulate in large masses in the stomach. The caseine of a portion of milk should be first peptonized, and then added to fresh milk. 3. Raw starch is inadmissible, and the practice of adding it to fresh milk, to break up the caseine, is wrong. The products of the complete digestion of starch, when taken in excess, cause indigestion. The administration of fully digested food to either adults or infants is bad for the digestive organs. 4. All nursing bottles should be boiled several times a day in order to destroy the germs of decomposition. Desiccated (partly peptonized) milk is often a convenient and efficient substitute for mother's milk. 5. Success in infant feeding depends largely upon the ability of the physician to individualize for each patient.

On motion of Dr. L. A. Sayre, of New York, amended by Dr. Lee, of Philadelphia, it was resolved that the Committee on Dietetics be continued and be instructed to present a report at the next meeting of the Association, embodying the general principles to be observed in a rational system of dietetics.

The consideration of three

AMENDMENTS TO THE CONSTITUTION,

which had been proposed at the last meeting, then came up for discussion.

The first amendment was that the so-called members by application should be such members of State, county, or district societies, as should present a certificate of good standing. They should have all the rights and privileges of permanent members, and should retain these privileges under the same conditions as the permanent members adopted.

The second amendment related to the Committee on Publication, and provided that the work of this committee should be undertaken by a board of trustees consisting of nine members, three of whom should be elected annually, to serve for three years. This board should have charge of all records, proceedings, memoirs, and other matters formerly referred to the Committee on Publication, and should also have power to appoint the Editor of the *Journal*; this was adopted.

The third amendment related to the substitution of a general Standing Committee for the present Committee on Nominations. This committee should consist of two members from each State and Territory, elected by the delegates present at each meeting. One member should be chosen each year to serve two years. The duty of the committee should be to present the names of the candidates for the various offices, but the committee could not present the name of any of its own members for any office.

The proposal of this amendment gave rise to considerable discussion, some of the speakers fearing that it would result in the formation of a ring, and in the eventual taking away from the members constituting the general body their political rights. It was finally moved, and carried, that the consideration of this amendment be made a special order for the next general session.

In the evening a reception was tendered the members of the Association by the citizens of Cincinnati in the Art Museum at Eden Park.

THURSDAY, MAY 10TH—THIRD DAY.

The general session was called to order by the President at 10 A.M. A communication was received from the Arkansas State Medical Society, containing a series of resolutions condemning

THE PUBLICATION OF QUACK ADVERTISEMENTS IN RELIGIOUS PAPERS,

which had been passed by that Society at its last annual meeting. On motion it was resolved that the American Medical Association endorse these resolutions and spread them upon the minutes of this session.

A communication was received from the Philadelphia County Medical Society, inviting the Association to hold its meeting next year in that city. The Chairman then presented the

REPORT OF THE COMMITTEE ON NOMINATIONS,

in which the following candidates were proposed for election. *President:* W. W. Dawson, of Ohio; *First Vice-President:* W. L. Schenck, of Kansas; *Second Vice-President:* Frank Woodbury, of Pennsylvania; *Third Vice-President:* H. O. Walker, of Michigan; *Fourth Vice-President:* J. W. Bailey, of Georgia; *Treasurer:* R. J. Dunglison, of Pennsylvania; *Secretary:* William B. Atkinson, of Pennsylvania; *Librarian:* C. H. A. Kleinschmidt, of the District of Columbia; *Trustees* (to fill vacancies): E. M. Moore, of New York; J. H. Hollister, of Illinois; and J. M. Toner, of the District of Columbia; *Members of the Judicial Council:* W. A. Phillips, of Kansas; A. M. Pollock, of Pennsylvania; W. C. Vanbibber, of Maryland; J. F. Hibbard, of Indiana; C. S. Wood, of New York; J. M. F. Gaston, of Georgia; W. H. O. Taylor, of New York; and G. L. Porter, of Connecticut; to deliver the Address on General Medicine at the next annual meeting: William Pepper, of Pennsylvania; Address on General Surgery: P. S. Connor, of Ohio; Address on State Medicine: W. H. Welsh, of Maryland. For the Committee on State Medicine one member was appointed from each State. Sub-committee to fill vacancies that might occur: J. B. Hamilton, William Brodie, and A. Garcelon. The candidates proposed were unanimously elected. It was announced that the Association would hold its next annual meeting in Newport, R. I., on the second Tuesday in June, 1889. Dr. H. R. Storer, of Rhode Island, was appointed Chairman of the Committee of Arrangements.

DR. E. M. MOORE, of Rochester, N. Y., then delivered the

ANNUAL ADDRESS ON SURGERY.

He reviewed the history of surgery from the earliest times, showing that many of the supposed novelties were in reality only revivals of the methods of the past. But in one particular more than any other the

PROGRESS OF MODERN SURGERY

was most remarkable, and it was one of prime and vital importance, upon which the success of operations in greatest measure depends; this was in the

TREATMENT OF WOUNDS.

Progress in the management of amputation wounds may be said to have begun with Paré and his ligature of arteries. At first a limb was amputated by a circular incision, the soft parts and the bone being divided at the same level; then it was thought advisable to cover the bone with integument, and this gave rise to the multiplicity of flaps of all shapes and size. The surgeon always had

TO MEET AND CONTROL HEMORRHAGE,

and it was strange to see how nearly the ancients approached the modern methods of hæmostasis without reaching them. A cord was tied tightly around a limb, but it was long before the tourniquet was devised. A number of bandages were wound around a member to expel the blood from it, yet it is only in our own day that

THE METHOD OF BLOODLESS OPERATION

has been perfected by Esmarch. Before the introduction of the ligature amputation wounds were necessarily left open, and the exposed surfaces were covered with all sorts of ointments. Galen, however, favored the application of a

COLD WATER DRESSING,

and Liston revived this method many centuries later, urging its general adoption in vigorous and characteristic language. After the employment of ligatures had superseded all other methods of controlling hemorrhages from the large vessels, attempts were made to secure primary union by immediate closure of the wound; but they were of very doubtful success until the introduction of antiseptic methods. As regards the question of

AMPUTATION FOR GANGRENE,

the speaker favored the selection of the red line of demarcation for the site of operation, when possible, and he believed the success was far greater in such cases than when the limb was removed at a higher point. In this he differed from most surgical teachers of the present day, the method being a return to that of ancient times.

GUNSHOT WOUNDS

were formerly regarded with the utmost dread, it being supposed that the leaden bullet was an active poison; but since the adoption of thorough antiseptics in wound treatment, surgeons had lost much of their fear in dealing with these injuries. In the matter of

OPERATIONS UPON THE ABDOMINAL CAVITY,

the same changes had taken place. It was no longer thought that the surgeon who dared to remove an ovarian tumor was no better than a murderer, for to such a degree of perfection had the methods of dealing surgically with the peritoneum been brought, that the mortality following laparotomy was now below that attending any other capital operation. Surgeons no longer dreaded to touch the peritoneum, for they had learned by experience that it was not injury that this membrane resented so much as it was dirt. Thorough and absolute cleanliness was the keynote of success, and this was the essence of antiseptic surgery. The name of Lister would be written by posterity alongside of that of Jenner, for he had added a word to the language which would ever remain there, although it was not necessary to use carbolic-acid gauze in order to practice Listerism. Perhaps nothing showed in a more striking manner the results of antisepsis than did the statistics of Volkmann regarding

COMPOUND FRACTURES OF THE LEG.

Of 885 cases of this nature, treated in the civil hospitals of Germany and England prior to the discovery of antiseptic wound treatment, 339 resulted fatally, while of 75 consecutive cases treated since the adoption of antisepsis there was not a single death. Many of these cases were complicated by wounds of the joints, and of those treated conservatively anchylosis had followed in but one instance. The speaker recalled an invitation that he had received fifty-one years ago from Professor Mutter, to see him perform

SUBCUTANEOUS TENOTOMY

of the tendo Achillis. The operation was vehemently opposed by many of the older surgeons of that day, Barton even refusing to be present and to be a witness of what he considered a most hazardous and unjustifiable operation. These men did not understand the great principle involved in subcutaneous surgery, and they little thought that this new method of operation was to be

THE FIRST STEP TOWARD ANTISEPSIS,

which is truly the legitimate descendant of subcutaneous surgery. The surgical world soon, however, awoke to the realization of a great advance in operative procedure, and subcutaneous methods were adopted in all possible cases, their application reaching the most extreme point when Guérin divided all the spinal muscles in his attempt to cure lateral curvature.

Dr. Moore then took up the subject of

COMPOUND DISLOCATION OF THE ANKLE-JOINT.

Amputation in these cases, he believed, was seldom necessary. Even in the most severe cases he advised the adoption of conservative measures, and, if the course of events rendered operation necessary, he would first resort to resection, reserving amputation as the last and most extreme measure. He looked upon

CONTINUOUS WARM-WATER IRRIGATION

as a most effective means of preserving the vitality of the contused soft parts, and preventing sphacelus, when resection was to be performed. The malleoli and their attachments to the astragalus should be preserved, if possible. At first the parts should be immobilized in plaster of Paris; but very delicate passive movements should be begun early and continued carefully from day to day. If such were done, the result would, in most cases, be a perfect preservation of the joint-motion.

The speaker then referred to the employment of hydrochloric acid, one part in twenty, in the

TREATMENT OF CARIES.

This had been recommended at a previous meeting of the Association, and he had tried it with some misgivings, but had found such great benefit to follow its use that he was led to count it as one of the greatest advances of the age in surgical therapeutics. He spoke of the attempts which had been made to secure a sterilized atmosphere in which to operate, which had, however, been hitherto unsuccessful. The spray was often bad, for it favored a deposit of minute foreign particles on the surface of the wound. A striking feature of the present age was that

THE REALLY GREAT MEN OF MEDICAL SCIENCE

were separated by no great distance from their colleagues; there were leaders, it was true, but their disciples followed closely in their steps, and at times even outstripped them. In conclusion, the speaker referred to the

VAST BENEFITS

which had been conferred upon mankind by the members of the medical profession, and by none more than by surgeons. These had long ago left the ranks of the barbers, and were now invading the field formerly regarded as peculiarly that of the physician. The spleen, the kidneys, the intestine, the liver, and the brain had all been subjected to the knife of the surgeon, and it was difficult to define the possibilities of modern surgery, which was an admirable blending of science and action.

The address was referred, with the thanks of the Association, to the Committee on Publication.

THE REPORT OF THE RUSH MONUMENT COMMITTEE

was then read. The response of the medical profession to their appeal had not been as ready as was to have been desired. Thus far but $709 had been received. The Michigan State Society had promised $100, and the Pennsylvania State Society had promised $400, in addition to the $100 already contributed.

THE REPORT OF THE TREASURER

showed a balance of $2,407.83 in the treasury.

The editor of the "Transactions of the International Medical Congress" announced that two volumes of the Transactions were now ready for distribution.

THE LIBRARIAN

reported that there were now seven thousand five hundred volumes in the library of the Association.

The amendment to the constitution, creating a

GENERAL STANDING COMMITTEE

to supersede the present Committee on Nominations, which had been made a special order for this session, was then brought up for discussion, and was, after a short debate, laid upon the table. A petition was presented by the Woman's Temperance Union, asking physicians to abandon the use of alcohol in their practice, and substituting therefor some other stimulant. In the evening the delegates were entertained at a complimentary concert in the Music Hall.

Friday, May 11th.—Fourth Day.

The general session was called to order by The President at 10.30 a.m.

Dr. H. P. Walcott, Chairman of the Massachusetts State Board of Health, delivered the annual

ADDRESS ON STATE MEDICINE.

He first related briefly the history of the State Board of Health of Massachusetts, which was established by legislative action in 1869. Its duties were at first advisory rather than executive, but in proportion as public intelligence in sanitary matters was quickened, the functions of the board were enlarged, until now it is charged to some extent with the power of enforcing the rights of the people to pure air, soil, water, and food, and preventing and punishing any violation of them. It is also intrusted with the business of gathering information concerning any matter pertaining to public health and diffusing such information among the people. Among the chief of its duties in this connection is the investigation of the causes and the prevention of infectious diseases. A comparison of the mortality statistics will show, in a measure, the effect which all this work has had upon

THE HEALTH OF THE PEOPLE.

The number of deaths from all causes, in proportion to the population, has changed but little during a period of thirty-six years, ending with 1886; but the percentage of deaths from zymotic diseases has almost steadily decreased, during the period that the State Board has been in existence, from 25.6 to 19.0; there has also been a general tendency, though less marked, in the direction of a decrease of deaths from constitutional diseases. The classification of

PREVENTABLE DISEASES

is as yet not well defined, and year by year, as the experience of sanitarians becomes widened, a larger and larger number of affections are found to be the result of influences that can be removed. This fact is illustrated in the case of

CONSUMPTION,

the prevalence of which was shown, twenty-five years ago, by a former president of this Association, Dr. H. G. Bowditch, to be largely influenced by conditions of soil, moisture, and land-drainage. The most marked reduction has occurred in the case of small-pox, which is a disease that is absolutely preventable by means of

VACCINATION AND RE-VACCINATION.

In demonstration of the saving of life in consequence of better sanitary conditions, the speaker offered a comparison between the results of ovariotomy and those following the labors of an intelligent and efficient board of health. The largest number of deaths in Massachusetts in any one year from ovarian dropsy was 51. In the single city of Somerville, the death-rate has been reduced, since the organization of a municipal board of health, from 22.86 to 16.68 per 1,000. Thus, the adoption of sanitary measures has saved more lives in one year, in a community of thirty thousand people, than could have been restored to health in the same period in a State of nearly two millions of inhabitants, by an operation which is justly regarded as one of the greatest triumphs of American surgery. It has been said by Dr. Russell, of Glasgow, that nothing is more conspicuous than the

HELPLESSNESS OF THE INDIVIDUAL,

under the conditions of civilized life, to secure the physical basis of health. How can any single individual in a crowded city detect and remove all possible causes of disease in the water, food, sewerage, and air contamination?

THERE IS NO HELP BUT IN CO-OPERATION

on the most extended scale possible—individual, municipal, State, and national. The individual must be compelled to give up the liberty to injure his neighbor; the city must be restrained from converting into a sewer the river which supplies water to the villages that cluster about its banks lower down in its course; no State should permit its own causes of disease, whether they are persons or things, to be transported into another State; lastly, the General Government should take cognizance of those causes of disease which can be controlled by no other power.

A SUFFICIENT SAFEGUARD

will never be established by voluntary associations on the part of persons, towns, States, or even nations. How, then, shall we organize for the protection of the public health? For the individual, the speaker maintained: Let the State give him some assurance that the legally used title of physician designates a person sufficiently qualified to give advice for the prevention and cure of disease; established, by direct provision of State law, local health authorities for each village, town, city, or county; and, to control all these local organizations, let there be a State board, clothed with ample powers. All arguments that have been used for the existence of State health authorities, Dr. Walcott believed, are also available for the creation and support of some

CENTRAL HEALTH AUTHORITY.

The question of form of this organization is one that may be left to the law-making powers—a board in which every State was represented might be cumbersome, but it could easily delegate its powers to a small and compact executive committee during the intervals between the necessarily infrequent meetings of the full board. The only alternative to this seemed to the speaker to be a single officer at the head of a bureau in connection with some one of the Departments at Washington; this central authority, however constituted, should have ample means for investigating into the State boards of health. There is still in legal existence

A NATIONAL BOARD OF HEALTH,

but, through the neglect of Congress, it is in a state of hopeless lethargy. This board entered upon its work with every promise of success, and it demonstrated that local, State, and national health authorities could profitably and harmoniously unite in suppressing an epidemic of yellow fever and preventing its spread from State to State, yet this did not save it from practical extinction. The failure of the board to survive the unjustifiable attack made upon it was due, in great measure, the speaker thought, to its organic form, embracing, as it did, members of the army, navy, and marine hospital service, and having a totally insufficient State representation.

In conclusion, Dr. Walcott urged the proper organization of some

CENTRAL HEALTH AUTHORITY,

whether in the form of a bureau of health or a board of health, provided, only, that some part of the great resources of the nation might be turned to the protection of that greatest of all property, human life.

The address was referred, with the thanks of the Association, to the Committee on Publication, from the Section on State Medicine.

A resolution was adopted, urging upon Congress the necessity of the immediate passage of the Senate Bill No. 2493,

TO PERFECT THE QUARANTINE SERVICE OF THE COUNTRY.

This bill has already passed the Senate, and is now pending in the House of Representatives.

The President announced that he had appointed the following members as

DELEGATES TO FOREIGN SOCIETIES:

R. H. Plummer, San Francisco, Cal.; H. A. Kelly, Philadelphia, Pa.; N. S. Davis, Chicago, Ill.; W. H. Myers, Fort Wayne, Ind.; A. E. Hoadly, Chicago, Ill.; F. E. Waxham, Chicago, Ill.; Alexander McAlister, Camden, N. J.; J. J. Chisholm, Baltimore, Md.; D. A. K. Stiele, Chicago, Ill.; J. V. Shoemaker, Philadelphia, Pa.; S. J. Jones, Chicago, Ill.; J. E. Owens, Chicago, Ill.; Ephraim Cutter, New York; L. A. Sayre, New York; C. C. Vaughn, Ann Arbor, Mich. The

REPORT OF THE COMMITTEE ON METEOROLOGICAL CONDITIONS

was presented by Dr. N. S. Davis, Chairman. The election of

OFFICERS OF SECTIONS

was then announced, as follows: Practice of Medicine, F. C. Shattuck, Boston, Mass., Chairman; G. A. Fackler, Cincinnati, O., Secretary. Surgery, N. P. Dandridge, Cincinnati, O., Chairman; W. Q. Roberts, Louisville, Ky., Secretary. Obstetrics and Gynecology, W. H. Wathen, Louisville, Ky., Chairman; A. B. Carpenter, Cleveland, O., Secretary. State Medicine, J. B. Lindsley, Nashville, Tenn., Chairman; S. T. Armstrong, Marine Hospital Service, Secretary. Ophthalmology, Otology, and Laryngology, G. E. Frothingham, Ann Arbor, Mich., Chairman; G. C. Savage, Nashville, Tenn., Secretary; Diseases of Children, J. A. Larrabee, Louisville, Ky., Chairman; C. J. Jennings, Detroit, Mich., Secretary. Medical Jurisprudence, W. Kiernan, Chicago, Ill., Chairman; — Evans, Baltimore, Md., Secretary. Dermatology and Syphilography, L. D. Bulkley, New York, Chairman; M. T. Corlett, Cleveland, O., Secretary. Oral and Dental Surgery, F. H. Rehwinkles, Chillicothe, O., Chairman; E. S. Talbot, Chicago, Ill., Secretary. The report

OF THE SPECIAL COMMITTEE ON CRIMINALITY OF FŒTICIDE,

and measures for its prevention, was read by Dr. Quimby, of Jersey City. The committee stated that the life of the fœtus begins with the first moment of conception, and it advised the enactment of a general law making the malicious procurement of an abortion without lawful cause the crime of murder. The report was referred to the Section on State Medicine. The special

COMMITTEE ON DUTIES COMMONLY EXERCISED BY CORONERS

made a report through its Chairman, Dr. Marcy, of Boston. The committee recommended a system of medical examiners, similar to that in vogue in Massachusetts. The report was referred, and the committee continued for another year. It was announced that the number of delegates registered was about 1,200.

A resolution was adopted extending the thanks of the Association to the professional citizens of Cincinnati for the cordial reception tendered them, and for the numerous acts of courtesy which the members had received personally and collectively. At the request of the Section of Ophthalmology, Otology, and Laryngology, a new section on otology and laryngology was created.

The meeting was then adjourned.

SECTION OF PRACTICAL MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY.

Tuesday, May 8th—First Day.

Dr. N. S. Davis, of Chicago, opened the meeting of the above section by announcing the death of Dr. A. B. Palmer, of Ann Arbor, the chairman-elect, and the unavoidable absence of the secretary, Dr. N. S. Davis, Jr., of Chicago.

The election of officers being in order, the following were elected: *Chairman:* Dr. W. C. Van Bibber, of Baltimore, Md.; *Secretary:* Dr. G. A. Fackler, of Cincinnati, O.

The topic for discussion was

PNEUMONIA: ETIOLOGY, PATHOLOGY, AND TREATMENT.

Dr. Van Bibber opened the discussion with a consideration of the mechanism of pneumonia and its treatment. Dr. Van Bibber's paper had two objects: First, an inquiry into the initial causes of pneumonia; and, secondly, the treatment of the disease. He said a few words in regard to the anatomical arrangements of the parts. By the term mechanism of pneumonia the author attempted to show, in a general way, how the different changes in the structure of the lungs are brought about, which are recognized during life, are seen after death by the microscope, and demonstrated by the scalpel.

He recognizes among the predisposing causes of pneumonia four, which are quite different from each other, and each one of which must produce the same effect, viz., congestion in the capillaries, by a different mode of action. They are age, cold, malaria, and alcohol. He arrives at the following conclusion: The predisposing causes, as the name implies, do not produce pneumonia, *de ipso facto*, but they have already worked such structural changes in the body that, upon further disturbance of the system, a congestion of the numerous pulmonary capillaries is more likely to occur than any other diseased condition. A study of these structural changes, brought about by the predisposing causes, gives advantages both in advisory prophylaxis as well as in treatment. The author introduced the discussion of the treatment of pneumonia with the statement from Fothergill, that "every new remedy almost is tried in turn for pneumonia. It is a disease particularly suitable to speculative medicine." He had determined to present the subject by means of

FOUR HYPOTHETICAL CASES,

one, a child of eighteen months; one, a youth of twenty-five years; one, sixty years of age, complicated with malaria; and one case seventy years old, complicated with old age, malaria, and alcohol. In the discussion of the cases much stress is laid on cupping over the roots of the lungs, between the shoulders, or, more particularly still, between the third and eighth dorsal vertebræ, in order that, by the laws of counter-irritation over affected parts, the circulation through the roots of the lungs may be kept entirely free and open. It is also a means of controlling, or at least of moderating, the effects of high arterial action during fever. It is valuable from the relief of pain and oppression it affords. The medicines recommended are only five in number, viz., muriate and carbonate of ammonium, the former acting upon the circulation in the capillaries, assisting to unload them when they become engorged, and as a resolvent, a general expectorant, and a diaphoretic; the latter acting as a stimulant, a resolvent, and as a remedy which prevents the coagulating or engorging of blood in the capillaries. It may also be used as a vehicle in inhalations.

ANTIPYRIN AND ANTIFEBRIN

seem to control the fever, diminishing the heat of the blood.

Digitalis, veratrum viride, strychnia, strophanthus, and other remedies, are valuable in the hands of those accustomed to their use.

In regard to

THE MECHANISM OF HEART-FAILURE,

Dr. Van Bibber remarked: 1st. There is diminished lung area, hence diminished supply of arterial blood. 2d. Exudation and engorgement in the lung. 3d. The amount of blood which arrives in the heart has to be forced through the obstruction. This brings a heavy weight upon the left ventricle. If this is continued the heart must fail.

DISCUSSION.

Dr. Whittaker remarked that he did not exaggerate if he stated that the last two years had been more eventful in the study of pneumonia than any period in the two thousand years preceding them. For they removed it from the general to the acute infectious diseases. All the errors that clung to the disease have fallen. It does not attack the vigorous and strong, but shows a predilection for the feeble. Cold is no longer considered a cause of pneumonia. Juergensen was the first to show where the disease belongs, even without a definite knowledge of the cause. The speaker then recited the discovery of various micro-organisms of pneumonia, selecting finally those of Friedlander and Fraenkel as the probable causative agents. We know that it may also be produced by other micro-organisms, as by the typhoid bacillus, or the staphylococcus of pus.

There is hence no poverty of material. May there not, then, be many forms of pneumonia? One has been isolated and called

CROUPOUS PNEUMONIA,

but may not this be resoluble into a number of kinds? Thus far it has been divided into primary and secondary pneumonia; the latter due to the invasion of the respective bacilli. Investigation has shown that in seventy to ninety per cent. of cases of true croupous pneumonia, the bacterium of Fraenkel, the diplococcus, is found. The physician is thus enabled to diagnosticate pneumonia by means of the bacterium twenty-four hours before the manifestation of physical signs. The speaker describes the process of staining. In this study we get some nice points as to treatment. The bacteria are sensitive to heat: 170° attenuates the bacteria of Fraenkel in twenty-four to forty-eight hours; 105° attenuates the bacteria of Fraenkel in five days; 104° attenuates the bacteria of Fraenkel in seven to eight days. This corresponds pretty well with the clinical history of a case of pneumonia. The fever may be the very agent destroying the disease. It has been observed that those were the most favorable cases in which the temperature was most pronounced. Danger is not on the part of the fever, but on the part of the heart, and the question is, whether it is not the best plan of treatment to sustain the heart. Let the fever alone. Be content with small doses of antipyrin or antifebrin to do away with any evil effects of high temperature. For the heart nothing is better than digitalis. If rapid stimulation be necessary, nothing is better than nitro-glycerine and black coffee, alcohol. Under such regime, the speaker had found, during twenty years' practice, the mortality of pneumonia reduced from twenty to ten per cent.

Dr. N. S. Davis thought it a curious fact that the

MORTALITY IN PNEUMONIA

of to-day is indubitably greater than that of forty-five years ago. If anything is established this very fact has so been, by statistics gathered not in hospitals only, but in among the population of the United States, city and country, in private and in general practice. As to the question of cold, it has been indubitably demonstrated that the disease prevails more during winter than summer months. He referred to the statements made by a prominent Canadian physician, in one of the early meetings of the Association of that Dominion, to the effect that during a practice of thirty years, he had adopted three plans of treatment. During the first of the three decades the treatment consisted of bloodletting. The second decade constituted the transition period from the bloodletting, antiphlogistic treatment, to the expectant plan; and the third the stimulant method. He found, in footing up his records, that the mortality was least during the first decade, and greatest during the last. The speaker dwelt at some length upon the benefits derived from bloodletting during the first stage, followed by cardiac depressants during the subsequent twenty-four to thirty-six hours. He cited cases in illustration.

Dr. Von Klein, of Dayton, O., had, during service in the Russian army, found that pneumonia prevails to a less extent in a climate in which the temperature is 50° below zero, than in our moderate climate. He believed in the judicious use of the lancet. He ascribed the increase in mortality to the fact that the people are not as robust as those of fifty years ago. They have changed their surroundings, habits, clothing, etc., and our treatment ought to be guided by the peculiarities of each case.

Dr. Octerlong, of Louisville, took issue with Dr. Davis in regard to increased mortality. During the time of mixed treatment, according to the statements of Skoda and Austin Flint, the results improved fifty per cent. J. H. Bennet, of Edinburgh, introduced the method of furthering the natural progress of the disease, with the result that the mortality was reduced to 1 in 36. The speaker had, on former occasions, depended upon local causes, that the changes were local, and that they were amenable to

LOCAL TREATMENT.

But, impelled by more extended observations, he had become a convert to the theory of pneumonia being an essential, specific fever due to a specific cause, probably the pneumo-coccus. He thought that a physician was rarely called to a patient during the first stage, but generally when the exudation had already commenced.

Dr. Jenkins, of Iowa, attributed the apparent increase in mortality to the improved facilities of diagnosis and the advances in our knowledge in pathology.

Dr. Baily, of Louisville, advocated decidedly the

USE OF STIMULANTS,

especially during the last stage.

Dr. F. C. Shattuc, of Boston, stated that although it was doubtful whether the increased temperature is a salutary process, yet he thought that more attention should be paid to the

CONDITION OF THE PULSE

than that of the fever. During the past the influence of temperature in pneumonia has been overrated. He has discarded the systematic use of antipyretics in this disease. It is a febrile affection of short duration, and he believed that the use of antipyretics, especially at the approach of the crisis, is dangerous when the heart's action is enfeebled, and this plan of medication may cause dangerous collapse.

In conclusion Dr. Van Bibber stated that he had received a letter from Dr. W. H. Welch, in which the statement was made that, "it is apparent that the evidence is not conclusive that either of the organisms is the infectious agent of croupous pneumonia;" certainly no such evidence has been presented as that which leads us to accept the tubercle bacillus, the typhoid bacillus, or the cholera spirillum as the cause of the respective diseases.

Dr. Frank Woodbury, of Philadelphia, Pa., spoke of

THE HIPPOCRATIC OPERATION FOR EMPYEMA,

and reported a case in illustration.

Dr. Morris H. Henry, of New York, in a paper entitled "My own Clinical Experience in the Administration of

IODIDE OF POTASSIUM IN THE TREATMENT OF SYPHILIS,"

prefaces his remarks with a few words on the value of mercury in the early, or what is termed the middle, period of the evolution of the disease.

In the discussion of the subject proper the essayist stated that the iodide may be administered in doses varying from 5 to 50 grs. every four hours; from 30 to 300 grs. in every twenty-four hours. He spoke of the value of the remedy in syphilitic rheumatism. The remainder of the paper dwelt upon the claims of various authors to the priority of the adopted treatment of late and inveterate lesions of syphilis by the administration of *large* doses of the iodide of potassium.

BACTERIOLOGY AND PRACTICAL MEDICINE.—All researches hitherto undertaken have aimed at learning the excitants of disease; very many of them have been discovered, and many have been profoundly studied, so that the cause of nearly all infectious diseases has been made known; but bacteriology has hitherto confined itself to these limits. Practical medicine, in the more limited sense—prophylaxis excepted—has gained very little therefrom; but it may be hoped that the medicine of the future will play quite a different part, in consequence of the deeper knowledge of the various bacteria and their properties. Many purely empirical drugs will be rejected, and in their stead will be employed those which bear directly upon the morbific agent, or which act by strengthening the resistance of the organism. Unfortunately, many questions still remain open. We know, for instance, very little of the way in which bacteria influence the physiological life of the organism. We cannot as yet determine why many micro-organisms, which are introduced into the body in enormous quantities with water, air, or food, do not give rise to derangements, or in what manner the really harmful organisms disappear from the blood, or organs of some animals. Of great importance for the practitioner are the facts that similar groups of diseases can be excited by wholly different micro-organisms. Abscesses are produced, for instance, by the action of staphylococcus aureus and albus, streptococcus pyogenes, micrococcus tetragenus, and others. Erysipelas following wounds depends not only on the streptococcus erysipelatis of Fehleisen, but also on other streptococci and micro-organisms. Pneumonia is not only excited by Friedlander's pneumococcus, but also by other bacteria. Two very similar diseases—cholera asiatica and cholera nostras—arise from two very different kinds of bacteria. There are other facts of still greater importance, such as mixed infections. Rosenbach found many very different bacteria in the same abscess. The same is the case with septic infection of wounds. Similarly, as Wiegandt has observed, a kind of streptococcus is occasionally associated with tubercle bacilli. Dr. Dunin has shown that certain complications of typhus depend on the presence of other bacteria, etc. When all these questions are solved, then our system of diseases will also be changed; we shall then no longer group them according to symptoms, but causes. There still remain many such questions unsolved. We do not know, for example, upon what depend the different results of experiments on animals when we inject small or large quantities of bacteria. Lastly, we also know very little of the reason why individuality plays so large a part in the manifestation of disease. Very interesting but unexplained is a research pursued by Wysskowitsch. He found that bacteria which had no effect on healthy animals excited diseases in other animals whose organism was slightly deranged. Thus, injections of staphylococcus excited endocarditis in animals whose heart-valves were injured. When all the foregoing and many like problems are solved, then it will become more easy to employ bacteriology in practical medicine, and then we shall learn to estimate rightly the great value of this new study.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 6, 1888.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. V. P. GIBNEY presented a patient with

CROSSED SPINAL PARALYSIS.

The case showed one of the most extreme types of poliomyelitis. The left arm was wholly powerless, except that fair motion was preserved in the hand. The right arm could be raised to a right angle with the body. The right leg was completely paralyzed, with the exception of very slight power remaining in the adductors of the thigh, and the atrophy was extreme. In the left leg the motions were nearly normal. The paralysis had appeared suddenly when the patient was about three years of age. The attending physician had made a diagnosis at first of scarlet fever. The treatment had been the application, for a long period, of electricity, together with mechanical support. By means of a brace, locking the knee-joint on the right side, the girl was able to walk fairly well. Her general health had been good until last December, when she developed a very marked degree of

ANÆMIA.

This had increased steadily, until now her pallor was extreme. An examination of the evening urine showed a specific gravity of 1.008, acid reaction, an excess of urates, and some albumin. The morning specimen had a specific gravity of 1.017, and contained urates, but no albumin.

DR. A. H. SMITH suggested a trial of the compressed-air bath, which had been said to yield excellent results in the treatment of anæmia.

THE PRESIDENT asked whether Dr. Gibney believed that there was any relation of cause and effect between the paralysis existing for so many years and the anæmia recently developed.

DR. GIBNEY did not think that there was. He thought it not improbable that the case was simply one of extreme chlorosis, which was of not infrequent occurrence in girls of this age.

DR. POLK asked whether any of the members of the Society had had any experience with inhalations of oxygen, combined with the internal administration of iron, in the treatment of anæmia.

DR. WALKER had used oxygen with iron in a number of cases with great apparent benefit. The patients inhaled the oxygen for from five to ten minutes two or three times a day, the iron being given in the ordinary doses three times a day.

DR. WILLIAM M. POLK then read the paper of the evening, entitled

ENDOMETRITIS TREATED BY DRAINAGE AND BY PACKING WITH IODOFORM GAUZE.

He referred briefly to the usual methods of treatment of endometritis, which, while differing among themselves in many respects, had one point in common, namely, that they were most unsatisfactory in their results. A consideration of the conditions present in endometritis should lead to the institution of a more rational therapy. In this affection there is an inflamed and suppurating surface lining a nearly closed cavity, and the conditions are almost exactly comparable to those present in an abscess with an opening of insufficient size for the free escape of pus. The discharge is retained in the cavity, bathing the already inflamed surfaces, keeping up the irritation, and preventing thereby any attempts on the part of nature to effect a cure. In the case of an abscess cavity with a small opening, the plain indications are to enlarge the opening and drain away all the irritating discharges as rapidly as they are formed, and a similar mode of procedure should be equally effective in the analogous condition found within the uterus in endometritis.

The speaker had adopted this plan in a number of cases, and had been exceedingly well pleased with the results obtained. His cases were as yet few in number, and it would be premature to assert that all cases of purulent endometritis could be cured by this method; but it was, at least, rational in theory, and the benefit thus far obtained by its application was sufficiently striking to warrant its further trial. His plan was first to dilate the os, if necessary, in order to give exit to the pus. This could be practised in most cases without danger, unless adhesions were present. Then, if the indications called for it, he used the curette freely, and finally secured an efficient drainage by the introduction into the cavity of the uterus of a strip of iodoform gauze. Several cases, in which this method had been employed, were reported.

DR. WALKER had had no experience in the treatment of endometritis by this method, but regarded it as worthy of trial. These cases were the opprobrium of gynecology, and any measure that promised to give relief ought to be tried.

DR. SHRADY asked whether there was disease of the tubes in any of the cases reported by the reader of the paper.

DR. POLK said that the tubes had previously been removed in one case, but the improvement following institution of drainage by the iodoform gauze was so speedy, that it could not be attributed to the natural process of involution, which might be hoped for in time after the removal of the tubes. He would say that the applications were made every few days for a month. He had no doubt that, in most cases, the main cause acting to keep up the disease was the stricture of the internal os.

DR. SHRADY said that the sequence of events was generally constriction of the os, endometritis, and salpingitis. To remove the tubes in such cases was to begin at the wrong end, to treat the result rather than the cause. It was certainly more rational to treat the causal condition, if possible.

DR. HUNTER had not had any experience in packing the uterus with gauze in this particular disease, but it was his constant practice to do so after scraping the endometrium for cancer of the uterus. He had tried in these cases a rubber drainage-tube, provided with a flange, but the tube could not be retained, and he was thus led to substitute gauze, and had been well pleased with its efficiency as a drain. He asked whether Dr. Polk had seen any instances of iodoform-poisoning in these cases. He had seen one case of poisoning by absorption of the drug through the walls of the vagina, but he had never seen an instance of death from iodoform-poisoning.

DR. WALKER had seen one case in which very alarming symptoms had followed the application of iodoform in cancer of the neck of the uterus.

DR. GIBNEY asked whether any of the members had had any experience with the

SUBIODIDE OF BISMUTH

in antiseptic dressings.

DR. SHRADY had used it somewhat extensively at one time, but saw no especial benefit from it except that it excluded the air.

DR. GIBNEY said that he had employed it in quite a large number of cases and was very much pleased with its action. It seemed to be as efficient as iodoform, and it was a very good thing both for the surgeon and for the patient to get rid of the odor of the latter drug.

DR. SEXTON asked whether the reader of the paper had noticed any increase in the amount of the secretion from the uterine cavity following the introduction of the gauze. He had seen a case of epistaxis in which the flow of blood was kept up, and even increased, by the capillary action of some absorbent cotton introduced with a view to arrest it.

DR. POLK replied that the secretion, or at least the discharge, seemed to be increased in amount at first; but it was only temporary and the discharge was soon reduced to its former quantity and then lessened.

Dr. Sexton said that he had not found much benefit from the use of absorbent cotton and gauze in the treatment of middle-ear disease, and had abandoned the use of these materials in such cases when they were accompanied with a discharge. In reply to a question concerning the utility of boracic acid in cases of this nature, he said that occasionally he had had considerable trouble with this substance by reason of its caking in the external ear.

The Society then adjourned.

THE SEVENTEENTH CONGRESS OF THE GERMAN SURGICAL SOCIETY.

Held in Berlin, April 4, 5, 6, *and* 7, 1888.

Herr v. Bergmann, President, in the Chair.

(Special Report for The Medical Record.)

Wednesday, April 4th—First Day.

The Congress was called to order by the President, who thereupon delivered the

PRESIDENT'S ADDRESS.

He referred to the grief of the nation over its loss in the death of the Emperor, and recalled the fact that this Society was the first scientific association founded after the creation of the new German Empire. The Emperor Frederick, he said, looked with favor upon the endeavor of the Congress to erect a monument to the memory of its founder, the late Professor v. Langenbeck, and the Empress Augusta had suggested the establishment of a Langenbeck House which should serve as a headquarters and meeting place for the Society.

Herr Koenig then read a paper on the

PROGNOSIS OF CANCER.

The results of operative interference in cancer were much better now than they were before the introduction of antisepsis. This was partly, no doubt, due to the fact that surgeons had now less fear of making too extensive an operation, and they accordingly removed without any scruples all the glands in the neighborhood of the tumor, whether they were infiltrated or not. The immediate results of the operation depend largely upon the seat of the disease. Amputation of the breast is seldom fatal, but resection of the rectum for carcinoma is not infrequently followed by death. One reason for this difference is doubtless the difficulty of keeping the wound aseptic after an operation upon the rectum. He referred to the statistics of cancer of the breast operated upon in his clinic, which had been published by v. Bergmann. Of 66 cases in which there had been a recurrence of the disease, 23 died within six months, and 30 more before the end of the year, making 53 within the first year. During the second year there were 7 deaths, 3 in the third year, and 1 each at the end of four, six, and eleven years. In some cases the recurrence was plainly to be attributed to the

GERMS SLEEPING IN THE CICATRIX.

In other cases the disease was brought back by the extension from already affected glands. In 15 operations for carcinoma of the rectum, the patients had control of the sphincter in 6. In general it might be said that, after operation for rectal cancer about ten per cent. of the patients might be expected to remain free from the disease for three years or longer.

The speaker then referred to the operation of

COLOTOMY

in cancer of the rectum. He thought that German surgeons did not practise this operation as much as they might. He had performed it twenty times. Six of the patients died immediately after the operation, 1 survived three years, 3 lived two years, and the rest died at varying periods within two years after the operation. The greater number of these lived in comparative comfort, and were able to retain their fæces even when suffering from diarrhœa.

Herr Petersen read a paper on a form of

PERFORATING DERMATITIS

of which he had seen five cases. This was a peculiar affection of the skin, occurring chiefly on the face and scalp, which resembled herpes tonsurans, yet was not the same in all respects. It appeared in the form of small, red, elevated spots of irregular shape, which soon became covered with dirty yellow crusts. The lesions did not bleed when these crusts were detached. Around them were formed numbers of pustules, which disappeared later, leaving little crateriform excavations. The hairs did not fall out nor become friable. Each of these little excavations discharged pus constantly. The patients complained of itching and smarting, but had no fever nor other constitutional symptoms. The treatment, which was successful, consisted in scarification and scraping with the sharp spoon, and the application of a paste composed of the oxide and chloride of zinc. Numerous and careful examinations showed the constant absence of the trichophyton tonsurans.

Herr Steinthal presented a communication on the

SURGICAL TREATMENT OF PERITONITIS,

following perforation of the intestine. He reported three cases of laparotomy for intestinal perforation, in all of which there was a fatal issue. He was not discouraged, however, by the result in these cases, and advised the performance of the operation whenever the symptoms of perforative peritonitis were present. Early interference gave the best promise of success.

Herr Lauenstein advised washing out the abdominal cavity, after operation, with a solution of salicylic acid, and then turning the patient over so as to insure a free return of the injected material.

Herr Frank reported two cases of peritonitis following

PERFORATION OF A TYPHOIDAL ULCER,

in which he had performed laparotomy. Both patients died.

Herr Doelger had operated four times for perforative peritonitis and had had one recovery.

Herr Fillmann had operated successfully in a case of perforating ulcer of the stomach. The incision was made along the free border of the ribs, directly over the seat of the lesion.

Thursday, April 5th—Second Day.

Herr Brieger made a demonstration of the

ACTION OF THREE PTOMAÏNES.

He injected into a rabbit a solution of *tetanine*, obtained from the amputated arm of a man suffering from tetanus. In about five minutes the animal exhibited all the symptoms characteristic of traumatic tetanus in the human subject.

The injection of a solution of *neurine* caused first a flow of a thick fluid from the nose; then profuse salivation appeared, and later the animal suffered from dyspnœa, became paralyzed, and died in convulsions.

The third ptomaïne was *mytilotoxine*, obtained from diseased mussels. When given to a man suffering from tetanus it caused a relaxation of the clonic spasms, but in animals it did not have the same effect. An animal poisoned with this toxine had head-drop, dyspnœa, convulsions, and paralysis.

Herr Fischer presented

THREE CASES OF TREPANNING.

The first patient was a man, forty-seven years of age, who had received a blow on the head followed by hemiplegia.

The skull was trephined and the wound healed readily, but later he suffered from very frequent epileptic attacks. The symptoms indicated a lesion of the central convolution. At the end of six years he was trephined again, the result being a perfect and lasting cure.

The second case was that of a woman, thirty-three years of age, who presented symptoms of abscess in the frontal lobe following otitis media. The skull was trephined, and, the hypodermic needle showing the presence of pus, the abscess was opened and drained. The following day there was a return of consciousness and of the power of speech, and in nine days the patient was able to leave the bed.

The third case was in the person of a boy, eight years of age, who had facial paralysis following a depressed fracture of the skull. The trepan was applied, and in one week the child was nearly well.

Herr Bergmann presented a patient showing the results of

COMPLETE LARYNGECTOMY

for carcinoma of the larynx. The operation had been performed three years ago, and there had been as yet no recurrence of the disease. The attempt had been made to introduce an artificial larynx, but it caused considerable discomfort, and the patient could not get accustomed to its use. He was, however, able to make himself understood in conversation by a fairly distinct whisper. He was able to swallow with ease, and took his food in the usual way. The speaker said that he had never been able to make a diagnosis of carcinoma of the larynx, with any degree of certainty, by means of the mirror alone, and he always made a practice of removing a portion of the growth and examining it under the microscope before venturing an opinion as to its nature.

Herr Hahn had performed the operation of

EXTIRPATION OF THE LARYNX

twenty-four times on eighteen patients. Six patients underwent a partial operation, and of these 2 died. Of the 12 patients upon whom total laryngectomy was performed, 2 were cured and the others died soon after the operation.

Herr Fischer reported a case of

RESECTION OF THE STOMACH,

for carcinoma. The patient was a woman, fifty-two years of age, who had a tumor near the umbilicus. The growth was movable and seemed to be in the small intestine, but when the abdomen was opened it was seen to be situated on the greater curvature of the stomach. The operation involved the removal of a very large part of the organ. It was successfully performed, and within one week the patient was able to take her nourishment by the mouth. She died five months later of perforating ulcer of the stomach. The autopsy showed such perfect union that the cicatrix could not be discovered.

Herr Bergmann presented a patient upon whom he had performed

RESECTION OF THE JEJUNUM

four times for carcinoma. The mesenteric glands had also been removed. The patient was now perfectly well, and had gained forty pounds since the last operation. The most careful examination of the abdomen failed to reveal the slightest swelling in any portion. The speaker felt justified, from the result obtained in this case, in making the assertion that

CANCER IS CURABLE.

Herr Lauenstein read a paper on the

HEALING OF WOUNDS UNDER A MOIST BLOOD-CLOT.

He had tried this method in a large number of cases, and thought that its range of applicability was limited. It should never be employed when it was desired to obtain union by first intention, and it was also inapplicable in operations upon the mouth or neighboring parts, in laparotomy, or in acute abscess. On the other hand, it was useful in small wounds of the head, in lacerated wounds with denudation of the tendon, after the removal of tumors, etc. The great advantage of Schede's method was that, as a general rule, only one dressing was necessary.

Herr Woelfler then presented a communication on

MUCOUS GRAFTS.

He reported three cases of impermeable stricture of the urethra, in which he had transplanted mucous membrane, after exsection of the cicatrix, with excellent results. He had first tried conjunctival and vaginal mucous membrane taken from a rabbit, but the pieces did not adhere. He then made use of membrane taken from the freshly amputated cervix uteri of a woman. A catheter was left in the urethra for five days, after which the canal was found to be patent throughout its entire extent, so as to admit freely a No. 20 Charrière sound. No further treatment was pursued, but after five or six months', examination showed that there had been no recontraction of the stricture. This, the speaker thought, was evidence that the transplanted strip of mucous membrane formed a part of the wall of the urethra, and did not contract like cicatricial tissue. He had obtained equally good results in a blepharoplasty and a rhinoplasty in which he had used portions of mucous membrane from the cervix uteri and from the rectum, taken from these organs when prolapsed. In other cases he had succeeded in securing adhesion of strips of membrane taken from animals. From his own experience he was able to confirm the observation of Thiersch that mucous membrane, when transplanted to a part normally covered by skin, became transformed into skin, but in other parts where mucous membrane was normally found, it remained mucous membrane.

Herr Fischer exhibited

THREE LARGE GALL-STONES

which had caused intestinal obstruction. One of these stones had been passed spontaneously on the third day, and another on the sixth. The third stone was removed by operation, and the patient died.

Herr Bidder presented a patient showing a typical hereditary

ARREST OF DEVELOPMENT OF THE BONES OF THE LEG,

the fibulæ being merely rudimentary, which had caused a very marked pronation of the feet, so that the dorsal surfaces looked outward. There was also absence of some of the toes, with the corresponding metatarsal bones, in each foot.

Herr Kuester reported four cases of

RESECTION OF THE TEMPORO-MAXILLARY ARTICULATION

for anchylosis. He dwelt at some length upon the etiology of anchylosis of this articulation, and reviewed the different operative measures which had been employed at various times for its relief. He did not favor Koenig's method, in which an incision was made along the inferior border of the zygomatic arch, as it did not bring the field of operation into view, but forced the surgeon to rely upon his finger as a guide.

Herr Thiem read a paper on

POSTERIOR LUXATION OF THE JAW.

It is generally asserted that posterior dislocation, without fracture of the lower maxilla, is possible, but this the speaker denied. He based his assertion on anatomical grounds. He reported seven cases of dislocation of the jaw to the left, which he had seen in five patients during a period of only two years. He believed that many cases which were supposed to be pseudo-trismus or anchylosis of the jaw were in reality old luxations.

Herr Petersen reported a case of

ISCHÆMIC MUSCULAR PARALYSIS.

The cases hitherto reported by Volkmann and Leser were all due to compression resulting from a plaster-of-Paris bandage; but in this case such a cause was clearly to be excluded. The patient was a girl, four and a half years of age, who was suffering from a complicated fracture of the arm. The member was put up in a simple, well-padded splint, in which it was retained for six weeks. Upon removal of the apparatus, the elbow, wrist, and finger-joints were found to be strongly flexed and immovable, owing, apparently, to a shortening of the muscles and tendons on the flexor surface. Dissection showed the presence of areas of degenerated muscular tissue resembling fibrous connective tissue. These were excised and, after massage, forcible extension under ether, and the application of electricity, a very marked improvement was obtained.

It was announced that, on account of the national mourning, there would be no banquet, but many private entertainments were given to the members by the residents of Berlin.

FRIDAY, APRIL 6TH—THIRD DAY.

HERR ISRAEL presented a patient upon whom he had performed

RHINOPLASTY

twenty-two months before. The operation had been done after Koenig's method of the transportation of osseous flaps for the correction of the deformity of

SADDLE-NOSE,

and there had been no return of the deformity, the cure seeming to be a permanent one. He reported also another case in which he had taken a flap, including periosteum and a thin lamella of bone, from the frontal region, just at the root of the nose, to construct a new organ after its destruction by a syphilitic process. The result was excellent.

HERR HELFERICH showed a student who had lost the tip of his nose in a duel, and for whom he had constructed a new one by flaps taken from the cheeks. The first flap, taken from the left cheek, was turned over so that the integumentary surface lined the nasal cavity, and a second one, from the right cheek, was twisted so as to bring the raw surfaces in apposition. There was no septum except a narrow strip at the lower orifice of the nose.

HERR KOENIG said that the first thing necessary in cases of

TOTAL RHINOPLASTY

was to construct a bony framework. This he had done in two cases successfully. It was difficult, however, to estimate correctly the proper size of the new nose. In one case he had made it a little too long, and in another one too short. After the formation of the bony portion, he covered the granulating surface with skin transplanted from a neighboring part. He made no attempt to form a septum, contenting himself with giving plenty of breathing space.

HERR WEHR presented some specimens proving the possibility of the

INOCULATION OF CANCER.

Sänger had denied that the inoculation of material taken from true carcinomatous nodules would give any positive results, but in so doing, the speaker maintained, he was in error. Herr Wehr had placed little pieces of carcinomatous material under the skin of a dog, and had seen tumors develop which grew for a while and then gradually disappeared. Microscopical examination of these nodules showed their structure to be carcinomatous.

HERR BERGMANN thought that the cancerous nature of a tumor which disappeared spontaneously was very questionable.

HERR THIERSCH read a paper on

INTUBATION OF THE LARYNX,

after O'Dwyer's method. He reviewed the early efforts of Bouchut in this direction, efforts which were disapproved by the Paris Academy of Medicine and had been forgotten, and then referred to the rediscovery of the method in America. At first, he was not inclined to give much credence to the reports of wonderful results obtained by intubation, but, after reading the papers presented at a meeting of the New York Academy of Medicine in June last, he had come to the conclusion that the method was of great value, and had determined to put it to a practical test. He had performed intubation in 32 cases of diphtheritic croup occurring in the Leipzig Hospital. Of these cases the dyspnœa was permanently relieved in 14, of which number 3 recovered. In 18 cases there was a return of the dyspnœa, and he was obliged to resort to tracheotomy. All of these cases terminated fatally. He attributed the poor results to the fact that the disease was of a very malignant type. In all the cases the immediate result of the introduction of the tube was an

INSTANT RELIEF OF DYSPNŒA,

but, as before mentioned, this relief was only temporary in about one-half of the cases. He thought intubation was specially indicated in cases in which the membrane was limited in extent, and in which there was not much swelling of the epiglottis. The inconveniences of the operation were that the almost constant presence of the physician was necessary, because of the accidents which were liable to occur at any moment, and that the presence of an open tube, only partially covered by the epiglottis, exposed the child to greater risk of

ASPIRATION PNEUMONIA

(Schluckpneumonie). The tube caused ulceration at times.

HERR REHN had performed the operation fourteen times, with four recoveries. In four other cases he had subsequently resorted to tracheotomy, but without saving the lives of the little patients. In but one of these cases was the child able to swallow well. In some cases he removed the tube several times, once or twice a day, in order to give the patient nourishment.

HERR ROSE was a strong advocate of

TRACHEOTOMY,

and had performed the operation 1,926 times for diphtheria, with a mortality-rate of 71.6 per cent.

HERR THIERSCH presented two patients showing the results obtained by

SKIN-GRAFTING

after his method. The first was a woman, aged sixty-six, from whose forehead he had removed a cancerous growth. The wound was covered with strips of skin removed by the razor from the thigh of a young man. In the second case, a large area was covered over by a number of small pieces of very thin skin. In both cases the results obtained were all that could be desired.

HERR SOCIN made use of large pieces of skin, from eight to twelve inches in length and nearly two inches in width. In order to prevent the formation of disfiguring cicatrices, he made the strips to overlap a little, and found that this not only caused a smaller cicatrix, but also promoted very materially the healing process.

SATURDAY, APRIL 7TH—FOURTH DAY.

HERR WAHL presented a communication on

FRACTURES OF THE SKULL.

He divided fractures of the skull into two varieties, according to their mode of production. When a hollow sphere, such as the cranium may be considered, is compressed on two sides, it yields to a certain extent; but, if the force is continued, its elasticity is exhausted, and a fracture takes place at some point in the convexity of the sphere between the sides pressed upon. This might be called a "bursting-fracture" (Berstungsbrüche). If the force is applied suddenly, there is not time for the elasticity to come into play, and the result is a depressed fracture. The speaker showed several skulls illustrating these different forms of fracture.

Herr Schlange presented some vertical sections of the pelvis showing the anatomical conditions found in

HYPERTROPHY OF THE PROSTATE GLAND.

The specimens showed a greatly enlarged prostate, all its dimensions being equally increased. The urethra was elongated and consequently narrowed, and the curve of the prostatic portion was exaggerated. The internal orifice of the urethra was situated at a higher level than in the normal bladder. The portion of the bladder behind the prostate formed a sort of diverticulum from which the urine could with difficulty be expelled.

Herr Koenig had often met with symptoms in the aged resembling exactly those ordinarily attributed to hypertrophied prostate, but at the autopsy the gland was found to be perfectly normal. In these cases there was a large

DEPRESSION IN THE BLADDER,

which could not be emptied of its urine, and thus the symptoms produced simulated those caused by enlarged prostate. He always preferred metallic sounds, and those of the largest possible calibre, sometimes even resorting to

MEATOTOMY,

in order to allow of the introduction of an instrument of sufficient size. He condemned the use of small sounds as dangerous.

Herr Kuester thought that one great advantage of the metallic instrument was that it could be kept thoroughly aseptic, and the production of small abrasions in the urethra was preferable to the use of a dirty catheter.

Herr Bergmann maintained that it was perfectly easy to keep an elastic bougie surgically clean, and he thought the risk attending the employment of metallic instruments was too great to be taken without the strongest of reasons.

Herr Waldeyer exhibited some anatomical preparations of the

ANTERIOR WALL OF THE BLADDER,

showing its relations to the neighboring parts, and proving that the danger of wounding the vasa dorsalia penis and the pudendal venous plexus in the suprapubic operation is a purely imaginary one.

Herr Neuber then read a paper on the

HYPOGASTRIC SECTION.

He recommended that the operation be divided into two parts. For the first operation he divided all the tissues down to the wall of the bladder, marking the intended field of operation in the latter by a silk thread. The wound was then tamponed, and at the end of six or seven days the vesical wall was incised. By this means all danger of infiltration of urine was avoided, and it was also easy to prevent opening into the peritoneal fold.

Herr Trendelenburg did not think that this mode of operating was an improvement on the older method. He had performed the high section about forty times, and had never seen an abscess or peritonitis result. The time required for the extraction of the stone was seldom more than two minutes.

Herr Helferich presented a communication on

RESECTION OF THE SYMPHYSIS PUBIS

as an aid in operations on the bladder. He had performed the operation three times, removing a portion of the pubic bones, and thereby greatly facilitating the subsequent section of the vesical wall. The ultimate results were good, the patients being able to walk well.

Herr Bergmann reported a case of

ENCEPHALOCELE

in a child, aged five months, in which a cure was obtained by operation.

Herr Alberti presented a child upon whom he had operated for a

MENINGOCELE

with good result.

Herr Koehler related a case of

GUNSHOT WOUND OF THE OPTIC NERVE.

There was total loss of sight in the right eye, and the internal and superior recti were paralyzed. Atrophy of the optic nerve supervened in the course of time.

Herr Sonnenburg reported a case of

OLD FRACTURE OF THE PATELLA,

with very wide separation of the fragments. He had recourse to Bergmann's method of chiselling off the tuberosity of the tibia, and carrying it upward. The fragments of the patella were then sutured. They united firmly, and the tibial tuberosity became attached at a higher level without any necrosis occurring. The function of the joint was almost perfectly restored, flexion only being slightly impeded, but this he hoped to correct by passive movements after more solid union had taken place.

Herr Kuester reported a case of

TRAUMATIC ANEURISM OF THE POPLITEAL ARTERY.

The patient was a young man, eighteen years of age, who was suddenly seized one day with a violent pain in the knee which compelled him to go to bed. When seen by the reporter there was a fluctuating, non-pulsating tumor in the popliteal region, which was supposed to be an abscess. It was incised, and found to be an aneurism. The artery was ligated, and the aneurism excised. Examination of the specimen showed a perforation of the artery by an osteophyte growing from the posterior surface of the tibia. The speaker had been able to find but three similar cases recorded in medical literature.

Herr Bernays, of St. Louis, reported three cases of

LIGATION OF THE VERTEBRAL ARTERY,

in continuity for the cure of epilepsy. The benefit following the operation was only a temporary one, and the speaker condemned the procedure as one unproductive of good results.

Herr Wollf reported a case of

CLEFT PALATE AND HARE-LIP

treated by staphylorrhaphy and uranoplasty. The first operation was performed on the second day, and the second when the patient was five months old. The result was good.

Herr Beely presented several novel

ORTHOPEDIC APPLIANCES.

The President then made a

CLOSING ADDRESS,

in which he congratulated the members of the Congress on the good work which had been done, and requested each one of them to collect for presentation at the next annual meeting, all the cases that he could of

PERMANENT CURE OF CANCER.

He assigned a limit of three years as one at the expiration of which, if still free from a recurrence of the disease, the patient might be pronounced cured.

The Congress then adjourned.

Immunity of the Chinese from Typhoid.—The interesting observation is made by Dr. Underwood, Customs Medical Officer at Kiukiang, China, that the comparative immunity of the Chinese in that region from typhoid fever, notwithstanding most of the factors favoring it are present in abundance, may be attributed to the fact that "cold, unboiled water is rarely or never used when tea can be had."

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Ninetieth Annual Convention, held at the Hall of the Faculty, Baltimore, Md., April 24, 25, *and* 26, 1888.

Dr. I. F. Atkinson, President, in the Chair.

Drs. G. L. Tanneyhill and R. T. Wilson, Secretaries.

(Concluded from page 507.)

Thursday, April 26th—Third Day.

Dr. Charles G. Hill, in a

SUPPLEMENTARY REPORT

from the

SECTION ON PSYCHOLOGY AND MEDICAL JURISPRUDENCE,

read a paper on

ALCOHOL IN ITS RELATIONS TO INEBRIETY.

After considering the number of drunkards in this country and the fact that twenty per cent. of all cases of insanity could be traced to inebriety, he treated the subject of alcohol as a food and as a narcotic, and then discussed the different diseases caused by inebriety, and the necessity of physicians paying more attention to guarding against this in their practice. He thought that this was a necessity which could not be too strongly insisted upon.

In the

DISCUSSION

which followed there was a lively debate on inebriety and drunkenness in general, which was discussed by Drs. John Morris, R. H. Goldsmith, and P. C. Williams.

Dr. Whitfield Winsey then read a volunteer paper on

SOME THOUGHTS ON BLOOD-LETTING,

in which he advocated the revival of this mode of treatment.

A lively

DISCUSSION

for and against this was carried on by Drs. H. Salzer, P. C. Williams, S. C. Chew, James Carey Thomas, J. W. Chambers, William Rickert, A. B. Arnold, and R. H. Goldsmith.

Dr. Charles O'Donovan, Jr., then read a paper on

A CASE OF URETHRAL STRICTURE WITH SEVERE AND UNUSUAL COMPLICATIONS.

Dr. Henry Salzer read a paper on

DIETETICS IN FEBRILE CONDITIONS.

Dr. J. H. Branham read a paper on

EXCISION OF THE LARYNX,

with a case.

Dr. J. H. De Wolf read a paper on

URGENT NEEDS OF THE MEDICAL PROFESSION.

The following elections took place for 1888–89:

President—Dr. John Morris.

Vice-Presidents—Drs. J. Edwin Michael and Thomas B. Evans.

Recording Secretary—Dr. G. Lane Tanneyhill.

Assistant Secretary—Dr. Robert T. Wilson.

Corresponding Secretary—Dr. Joseph T. Smith.

Reporting Secretary—Dr. William B. Canfield.

Treasurer—Dr. W. F. A. Kemp.

Menstruation in Old Age.—Dr. R. T. Knox reports the case (*Daniel's Texas Medical Journal*) of a woman who ceased menstruating at thirty-five. At the age of seventy-six she began menstruating regularly again, and has continued to do so for the past two years.

Correspondence.

THE GERMAN SURGICAL CONGRESS.

To the Editor of The Medical Record.

Sir: On the day preceding the formal opening of the Seventeenth Congress of German Surgeons, the Langenbeck Memorial Celebration was held in the "Philharmonie." The large hall was beautifully decorated and draped in mourning. The background of the stage was a grove of tropical and hot-house plants, and in the centre stood the life-size bust of the lamented von Langenbeck. Upon either side were seated the members of the executive boards of the German Society for Surgery and of the Berlin Medical Society. All the celebrated medical men of Germany, with but few exceptions, were in the audience, among them Esmarch, Thiersch, Trendelenburg, Miculicz, Waldeyer, Gerhardt, Du Bois Reymond, König, Helmholtz, Schede, Bardeleben, Schönhorn, Hahn, Braman, etc. The entire ministerial cabinet of the Emperor, the chief medical officers of the army, and also the Grand Duke of Baden, a brother-in-law of the present Emperor, were seated among the audience. The ceremonies were opened by the production of Mendelsohn's great chorus, op. 116, after which Langenbeck's successor, Professor von Bergmann, stepped upon the rostrum and delivered the oration. It was a masterpiece of biographical composition, and left a decided impression on the hearers. The exercises were closed by another chorus, and lasted in all something over one and a half hour.

The members of the German Society for Surgery assembled at nine o'clock in the evening for an informal lunch at the Hôtel du Nord. At one o'clock on Wednesday, Professor von Bergmann formally opened the Seventeenth Annual Congress of Surgeons in the Aula of the university. The hall proved almost too small to seat all the members and guests who were present. Ten years ago, when a pupil of von Langenbeck, I had joined this Society, it then had a membership of about 250. This number has now been doubled, and there were over 450 members present at the opening. The Society is looked upon, the world over, as facile princeps in its department of medical science, and its volume of transactions annually registers, either as original work or discussions, the most advanced surgical researches and experiences.

The Society has become wealthy, and at the present meeting papers of incorporation were made out and signed; the object being the erection of a building in the centre of the city of Berlin, to be called the "Langenbeckhaus." This will contain the hall, to seat eight hundred persons, a library room, museum of surgery, and laboratories. The rules for admitting members will be made more stringent, because membership will now be ownership in a valuable piece of property.

Among the most important papers read were one by König on the prognosis of cancer. One by Steinthal, Czerny's assistant, on surgical treatment of peritonitis following internal perforations. Schede's method of treating wounds, by allowing them to fill up with an aseptic blood-clot, gave rise to an animated discussion, during which some priority questions and jealousies cropped out between rivals, in a most amusing and refined manner. These questions were fought out impersonally, purely facts and objective statements being permissible. The general opinion was that Schede's method was nothing absolutely new, but that he had drawn attention to it in a manner that made an impression all over the world. The method was generally endorsed for a certain class of cases, especially of minor operations. Rosenbach's paper, proving conclusively that suppuration can be established notwithstanding the preservation of perfect asepsis, was perhaps as important a contribution as was produced at the Congress. Schimmelbusch demonstrated the new facts lately discovered concerning thrombosis.

At the morning sessions no papers were allowed to be read, the demonstration of patients, specimens, and short communications and discussions only being in order.

Americans will be pleased to hear that O'Dwyer's intubation was discussed and demonstrated in a matter-of-fact way by the eminent Thiersch, of Leipzig, and by Rehn, chief surgeon of the City Hospital in Frankfurt. Both gentlemen recommended further experiments with the method, and both feel that great improvements can be made in the instruments. Thiersch's results in thirty-four cases were not up to the twenty-seven per cent. claimed by O'Dwyer, but still he did not throw doubt upon the statistics in any way.

The only American member who spoke at the Congress was your correspondent, who made a report on the ligation of the vertebral arteries for the cure of epilepsy. After his report, in which he took the ground that the operation must be abandoned because it fails of its purpose, and is only of temporary benefit to the patients, the chairman, v. Bergmann, requested him to explain the performance of the operation anatomically, which he did.

By all odds, the most interesting demonstration was the one by Brieger. He exhibited the ptomaines discovered and chemically isolated by him, and by hypodermic injection showed their effects on animals. These substances are certainly the strongest and most deadly poisons known to us, and since they are the result of the life-functions of bacteria and micrococci, it is believed we shall soon be able to understand more about the deadly infections caused by these organisms.

On Sunday after the closure of the Congress, von Bergmann gave a fine dinner at his palatial residence, to which I had the honor of being invited, together with about thirty distinguished medical men, and about fifteen ladies. It was an elaborate affair, and most elegantly and tastefully served. The general surgeons of various armies were present, and among all the titled people a young American surgeon might have been overlooked, only for the great affability and social tact of the host and hostess.

I have noticed during the Congress that there is no personal favoritism, and no national chauvinism. All men meet here on the level of science, and are rated according to their deserts, judged by their published work. I think that to be the author or discoverer of some new surgical procedure, or of some new observations in any branch of medicine, would go farther to give anyone the entrée into scientific and social circles than any letters that might be brought.

The prejudice against Mackenzie is gradually disappearing in Germany. Among the new things that I brought over with me, was some moist antiseptic cotton, arranged between layers of gauze, which I had had made for me in New York. I showed it to von Bergmann this morning, and he was so much pleased with the article that he took it, saying he would use it on the Emperor's throat, where there was considerable secretion just at present. The throat disease is as little understood over here as it is in the United States, by the physicians generally. It is considered bad taste to express an opinion, since no authentic information is at our command. From a remark of Bergmann's, I should judge that there is little chance for the ultimate recovery of the patient.

Yesterday I assisted Braman at his polyclinic. The material is simply immense. For instance, four cancers of the breast in one afternoon; there are also four cases of cancer of the bladder in the hospital at the present time. Braman is von Bergmann's right bower, and operates perhaps as much as any man in Berlin. He is a most amiable and friendly gentleman, and always ready to show anything he has in the hospital. A. C. Bernays, M.D.

Berlin, April 10, 1888.

WHY THE CROWN PRINCE HAS ONE ARM SHORTER THAN THE OTHER.

To the Editor of The Medical Record.

Sir: Under the heading "Why the Crown Prince of Germany has One Arm shorter than the other," The Medical Record, in its last issue, publishes a story from a correspondent which is absolutely the contrary of the truth from first to last—if I am allowed to judge from personal communications with the late Professor Eduard Martin, with whom I was associated for nearly four years. One day I took occasion to ask him in regard to the rumor that Prince William's left arm was broken during delivery. He positively denied it, and told me that the baby was born with a *congenital atrophy* of the left arm. The other facts are these: When the present Empress Victoria anticipated her first confinement, it was decided to have Martin as the accoucheur, who was not long ago called to Berlin to fill the professorship left vacant by the death of Dietrich Wilhelm Heinrich Busch; besides, she had a midwife with the name of Katharine Stahl, and as her regular body-physician Dr. Wegner, who still holds the same position. When labor set in, the midwife, after examination, made the diagnosis of occipital presentation, with which Dr. Wegner concurred; but, instead of notifying Dr. Martin at once, they waited and waited, possibly wishing not to share the honor with somebody else of having the princess delivered. But when labor made no progress, after the bag had been broken some time, Martin was sent for.

He found breech presentation, and had to resort finally to extraction, which was extremely difficult. But notwithstanding his success, Martin was never called upon again. All the later confinements were conducted by Queen Victoria's English body-physician and the same German midwife. It was a current rumor in Berlin that Martin had broken the baby's left arm, and either overlooked it or not mentioned it, trusting that it would heal spontaneously; and that for this reason he was dropped.

In regard to the "hereditary deafness," it is a well-known fact that the present Crown Prince contracted otitis media, following measles, two years ago.

Respectfully, B. Scharlau, M.D.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 29 to May 5, 1888.

De Loffre, A. A., Captain and Assistant Surgeon. Granted leave of absence for six months on surgeon's certificate of disability, with permission to go beyond sea. S. O. 99, A. G. O., April 30, 1888.

Edie, Guy L., First Lieutenant and Assistant Surgeon. Now under orders to report for duty to the commanding officer, Fort Douglas, U. T., will accompany the 8th Cavalry from Department of Texas to Department of Dakota, and upon completion of this duty, will proceed to Fort Douglas. S. O. 99, A. G. O., April 30, 1888.

McCaw, William D., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Leavenworth, Kans., and ordered for duty at Fort Crawford, Colo. S. O. 48, Department of Missouri, May 1, 1888.

Rafferty, Ogden, First Lieutenant and Assistant Surgeon (recently appointed). Ordered for duty at Fort Clark, Tex.

Lauderdale, John V., Captain and Assistant Surgeon. Ordered from Fort Clark, Tex., to Fort Davis, Tex. S. O. 98, A. G. O., April 28, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 5, 1888.

Hord, W. T., Medical Director, and Woolverton, T., Surgeon. Ordered as delegates to represent the Medical Department of the Navy at the Meeting of the American Medical Association, May 8th, at Cincinnati, O.

Bradley, George P., Surgeon. Ordered to Navy Yard, Brooklyn, N. Y., without delay.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 5, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	6
Scarlet fever	230	24
Cerebro-spinal meningitis	8	9
Measles	117	6
Diphtheria	168	49
Small-pox	21	6
Yellow fever	0	0
Cholera	0	0

The Medical Association of the State of Alabama.—Dr. Jerome Cochran, Senior Censor of the Medical Association of Alabama, referring to a recent editorial on the subject, writes: "Membership in the Medical Association of the State of Alabama can be obtained in only one way, namely, by first securing membership in some county medical society. There are sixty-six counties in the State; and in everyone of these sixty-six counties there is a county medical society; and in the constitution of every one of these county medical societies there is a section adopting the Code of Ethics of the American Medical Association. Moreover, the Code of Ethics of the American Medical Association is published at length in our Book of Rules, and is made of obligation by the constitution of the State Association. Surely it is not possible to give the Code of Ethics stronger endorsement than this. With us 'a medical education' sufficient to pass our examinations 'qualifies a man to be legally a doctor,' even as you say. But a man may be a legal practitioner and at the same time under the ban of the profession for ethical misconduct. In other words, legal recognition does not involve ethical recognition. In the meantime, the number of irregular doctors in Alabama is so small as to be of very little importance. Irregulars may pass our boards of examiners, but our standard is so high that such irregulars are very apt to merge themselves in the regular profession. We regard our law as ideally perfect. If we could have it amended according to our wishes, we would be at a loss to suggest any change. We would not know how to make it better; and we have nothing further to ask of the State but to let us alone."

A Portrait of the late Professor James L. Little, M.D., has been painted for the Post-Graduate Medical School, and may be seen in the reading-room of that institution.

The late Dr. E. G. Loring.—At a special meeting of the Board of Surgeons of the New York Eye and Ear Infirmary, held May 2, 1888, the following resolutions were adopted:

Resolved, That in the sudden death of Dr. Edward Greeley Loring, Jr., the surgical staff of the New York Eye and Ear Infirmary have lost an able and skilful colleague, who for nearly fourteen years has been a surgeon in the Ophthalmic Department of the institution. His kindly and lovable personal qualities were most attractive, and in his death we feel keenly the loss of a genial, frank, and warm-hearted friend. In his professional attainments he was most eminent; enthusiastic in his devotion to his special field of work, and, as one of its most distinguished exponents, he was justly esteemed an authority. We greatly deplore the cessation of his labors while still in the full enjoyment of his powers, which were enriched by a large and carefully digested experience. As an author, he was remarkable for his acute observation and logical reasoning, while the clearness of his style gave evidence of the directness of his thought. By his death scientific ophthalmology has lost an ardent and successful disciple, while the community has been deprived of the services of a skilful counsellor and practitioner. The surgeons of the New York Eye and Ear Infirmary desire thus to give expression to their feeling of affection and respect for his memory, and sympathizing sincerely with his family in their loss, offer them their respectful condolence.

Resolved, That this minute be entered on the records of the Board of Surgeons of the New York Eye and Ear Infirmary, and that a copy be sent to the family of Dr. Loring.

Chas. Stedman Bull,
Gorham Bacon,
Morris J. Asch, *Committee.*

The late Dr. C. R. Agnew.—At a meeting of the Board of Governors of the New York Skin and Cancer Hospital, the following preamble and resolutions were adopted:

Whereas, By the hand of an overruling Providence this institution has lost, in Dr. Cornelius Rea Agnew, one of its original incorporators and an earnest supporter, as well as an efficient consulting surgeon;

Resolved, That the Board of Governors of the New York Skin and Cancer Hospital desire to express their profound admiration of the peculiar and noble traits of character possessed by Dr. Agnew, and the very great loss which the institution has sustained in his early removal from our midst.

Resolved, That this preamble and resolution be entered upon the records of the institution, and that a copy be sent to the family of Dr. Agnew and to the medical journals.

The Health Board of the city of New York passed the following:

Whereas, It has pleased Almighty God to remove Dr. C. R. Agnew from this life; and,

Whereas, the late Dr. C. R. Agnew had endeared himself to all by his disinterested public spirit, and his unswerving fidelity to just principles of public health; be it therefore,

Resolved, That the death of Dr. C. R. Agnew has deprived the people of this city of a vigilant and wise advocate of its sanitary rights and requirements, and also deprived this Department of a conscientious, impartial, and fearless counsellor.

Resolved, That these expressions be spread in full on the minutes of this Department, and that the President be directed to express to the family of the deceased the sympathy of this Department in their sad bereavement.

(A True Copy.) April 26, 1888.

Dr. Scanes Spicer has been elected Physician to the Department for Diseases of the Throat, St. Mary's Hospital, London.

Dr. Otis' Article.—Leiter should have been credited with the invention of the cystoscope, and not Lister.

Professor Paget carries in his obstetric bag an ergot-mill, resembling a small coffee-mill, compact in form, and designed to grind up ergot freshly for use. He claims that only the freshly pulverized ergot is reliable, and he thus secures it when wanted without depending on tincture and other liquid preparations, fetched from the druggists.

Original Articles.

COMBINATION OF CARDIAC NEUROTICS.[1]

By W. H. THOMSON, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, UNIVERSITY OF NEW YORK; PHYSICIAN TO THE BELLEVUE AND ROOSEVELT HOSPITALS.

While physicians have been long accustomed to combinations of different drugs to act in unison toward producing a given action on gland-secretion, analogous combinations of neurotics have not yet been very definitely or generally established in practice. Each of the six purgatives employed in the pil. cathart. comp., for example, is too small in quantity to exert more than a moderate amount of its separate or specific action, but yet it is able so to add its own cathartic property to the similar action of the others that we virtually obtain, by the combination, a new medicine, which operates without some of the disadvantages of the single free action of either one of the ingredients. The principle which underlies this practice is, that the different agents will re-enforce or intensify an effect which they have in common on a given function, while their separate and, it may be, antagonistic, actions, are either of little effect in comparison, or even may be neutralized in the combination. Thus, both opium and ipecacuanha have singly a moderate diaphoretic property; when united, that property is more than doubled, and may be still further promoted in febrile cases by the addition of aconite. Calomel, again, acts only slightly on the kidneys, but, along with squills and digitalis, it assists each of these in making the most certain diuretic known.

It appears to me that this principle may be expected to apply particularly to neurotics, because their action, instead of involving the whole nervous system in one kind of operation, is, on the contrary, limited in each case to single effects on particular nervous functions without involving directly any others. We may, therefore, be thus enabled to secure some special effect by intensifying a given property of one neurotic by a similar property in another, though in other actions they may be more or less antagonistic. For it should be remembered that such antagonism has no resemblance in its nature to chemical incompatibility, but is throughout a difference of impression on some nervous function, and hence may be not only very variable in kind and degree, but may not extend to any other nervous function whatever. The conception, indeed, that one neurotic can be the complete antagonist of another, in the fashion that chemical antidotes neutralize each other, is a serious mistake, and has done more than anything else to prevent the proper recourse to their combinations in practice. This misconception arises from regarding neurotics in the light of the old definition, that "they are medicines which act on the nervous system;" a definition which implies that the nervous system is an organ, like the stomach or liver, which can be spoken of as a unit, and, therefore, as stimulated or depressed as a whole. The true definition of a neurotic is "a medicine which affects *some* functions of the nervous system," because even the most powerful or widely operative members of the class act specifically only on a few of the many different functions of a system which has a greater number and a greater diversity of functions than the functions of all the organs and all the textures of the body put together. In fact, progress in the knowledge of the different neurotics has been almost wholly in the direction of finding just what centres or functions are affected by them out of a multitude of functions which they do not affect at all. So far, therefore, from speaking of them as universal agents of any sort, one should even guard against being misled by the terms used to denote their actions when they appear to be similar. Thus, ammonia and digitalis are both spoken of as cardiac stimulants; strychnia and ergot as spinal stimulants, etc.; but it is plain that the "stimulation" in each case is quite different in kind from that of the others, not only because the functions affected are different, but also because the process itself may be different, and the effect of one may be direct and of the other indirect, in producing the characteristic operation.

In keeping, also, with the physiological law of the nervous system, that, so far from acting as a unit, it constantly presents examples of functions which are antagonistic or inhibitory of one another, so that when one is in action others are in abeyance, we have neurotics which are at the same time both stimulants and sedatives, according to the separate functions which they simultaneously affect. Thus, while opium stimulates certain cerebral ganglia, it paralyzes the gastro-intestinal secretory nerves; and, again, while checking secretion in the alimentary canal, it increases the secretions of the skin. Alcohol, while it stimulates certain brain-functions and also the heart, at the same time, not subsequently, as used to be taught, paralyzes general sensation, so as to make the excited man uncertain of the exact whereabout of his legs. Such names as "stimulants," or "sedatives," therefore, should no more govern our conceptions of neurotics than such a name as "tonic" should influence our prescription in other cases. The separate effects of neurotics are often so independent that the most seeming opposites easily may be made to promote that which they have in common, without any interference with that common action by their other differences, just as opposite views in politics may not prevent two men from being good partners in business. Thus the initial action of opium and of belladonna on respiration is so antagonistic that in the first stage of poisoning by either of them the one can be employed to counteract the effect of the other on that particular function. But, on the other hand, both have much the same sedative action on another function, so that each may be correctly termed an analgesic, and for this purpose their combination is often quite advantageous. Moreover, the counter action of these two agents is itself limited to a particular condition of the function acted upon, and no longer obtains when that condition has ceased. Thus I have known of belladonna being given freely in opium-poisoning when, in the state of the patient, it would do nothing but mischief. For in the latter stages of opium-poisoning we have all the symptoms of collapse from exhaustion by overstimulation. The contracted pupil relaxes and may be widely dilated; the pulse, from being strong, regular, and full, in the first stage, becomes weak, irregular, and small; the inspiration, from being powerful and deep, becomes shallow, etc. Belladonna now will but intensify these symptoms and hasten the fatal conclusion, for it should be given only when certain special functional effects of opium are present, which its own particular functional effects will then, and only then, antagonize, and not when those opium-effects have disappeared. Special antagonism, therefore, in neurotics, does not exclude special co-operation, and, as in the glandular medicines, we may hope to obtain by such co-operation a more effective joint action than either, singly, could produce.

---

[1] Read before the Section of Materia Medica, New York Academy of Medicine, March 23, 1888.

I have long thought that, in the case of the nervous functions of the heart, associated as they are so intimately with the nervous functions regulating the blood-vessels, we had a promising field for bringing these principles into practical use. Moreover, there is no one class of nerve-functions which is so easily, or which has been so fully, studied of late years as that of the nerve-functions regulating the circulatory system. We know here both the mechanism which increases and that which decreases the frequency, force, and volume of the circulation, so far as nervous influence is concerned, better than we know about any other nervous work done in the body; and hence can entertain more definite conceptions about the action of cardiac and of vascular neurotics, than about any other neurotic actions, as the three medicines which we now proceed to mention will demonstrate.

Digitalis, when I first studied the materia medica, was classed among the heart-sedatives, because it slowed the action of the heart, made the pulse small, and often intermittent. The influence of names was then strikingly illustrated in this case by the recommendations for the use of this drug in disease, as they were based upon the meaning of the word "sedative," so that it was advised to give it for the same purposes, as far as the heart and circulation were concerned, as aconite or veratrum viride. Just now the same wrong influence of names is often illustrated in the recommendation of digitalis as a heart-tonic, when it is no more a cardiac tonic, in the sense that iron is, than it ever was a heart-sedative. What digitalis does do with the heart, so long as its influence lasts (which is necessarily temporary, because it is a neurotic), is to increase the contractility of the heart under certain conditions, in a cramp-like and rather irregular fashion, at the expense of its proper rhythmical relaxation, so that it interferes with the diastole while prolonging the systole. In a simply dilated heart this prolonged contraction is of great service, because, for the time being, the heart-cavities are brought more nearly to their normal state. We all know now, however, that one of the commonest causes of cardiac dilatation and failure is not to be found in the heart at all, but rather in an obstructed arterial circulation. It is probable that arteries, narrowed in their calibre, are the cause of cardiac hypertrophy and subsequent dilatation, three times in adults, to valvular disease of the heart itself once, and just here it is that the employment of digitalis in heart-failure often disappoints us most signally; for, unfortunately, while it increases the contractile power of the heart, it also contracts the arteries, and thus often adds as much obstruction to the circulation in that way as it aids the circulation by its increase of the heart's propulsion; a fact often illustrated in cases of dropsy in Bright's disease, where the condition of the systemic arteries is the primary cause of the anasarca.

It is in just such cases that nitro-glycerine can help us to administer the digitalis with more than double the beneficial effect of the administration of digitalis singly. Nitro-glycerine, by its universal and prompt relaxation of the whole arterial system, makes every stroke of the ventricles, stimulated by digitalis, not only more powerful but also far more effective in completing the systole with a short and heart-emptying contraction. Meantime, by its action in paralyzing the inhibitory action of the vagus, it insures a more rapid diastole, and, in many instances, I have found the intermittency caused by digitalis to disappear as soon as the effect of the nitro-glycerine is felt. The effect of this upon the anasarca in these cases is about as complete and gratifying as any remedial operation with which I am acquainted. But, on the other hand, the influence of nitro-glycerine alone, as I have noted in a number of instances, is almost *nil* on the dropsy, however much it often seems to have a beneficial influence on the secretory action of the kidneys by increasing the specific gravity of the urine.

In the new remedy, strophanthus hispidus, the profession, without doubt, has received a great addition to the list of cardiac stimulants. It is not our province now to enter upon the detail of the properties of this drug, except so far as to state that for functional derangements, like palpitation, we know of no superior to it, and that it has a particular effect to increase the power of the heart's contraction in a more regular and uniform, though not so powerful, manner as digitalis does. Meantime its contraction of the systemic arteries is very much less than that of digitalis, and its effect in increasing the specific gravity of the urine in chronic Bright's disease is much greater. I have never, in fact, succeeded in this respect with any other drug as with strophanthus. On the other hand, its combination with nitro-glycerine gives very much the same results on the circulation as the combination with digitalis, just mentioned, does, and hence I often give moderate doses of all three agents for the indications above specified in chronic obstructive conditions of the systemic circulation.

But it is in severe cases of acute disease that we meet with the most signal illustrations of the advantage of the combined action of cardiac neurotics. To prevent heart-failure until the patient can tide over the crisis becomes frequently the anxious problem in pneumonia, in sudden prostrations in fevers, in peritonitis, when the effect of shock in causing general arterial closure is so plain as a cause of cardiac exhaustion, and in many other cases of like conditions, and, I have no doubt, many practitioners will welcome some addition like this to the regulation brandy-and-ammonia prescription for such emergencies.

In illustration of my remarks, I now beg leave to cite in brief the histories of patients with both chronic and acute affections who have been so treated in my wards in the Bellevue Hospital during the past winter, as they are reported by my house-physician, Dr. E. J. Lorenze.

Case I. *Cardiac dilatation; general anasarca; bronchitis; hydrothorax; discharged improved.*—J. M——, aged fifty-nine, English, printer, widower; admitted December 8, 1887. Patient has been suffering from a chronic bronchitis for over six months. It became worse two days before admission. Headache, to which he had been long subject, had become more severe than usual. His urine became scanty and almost black in color. Had slight œdema of the legs for four months previously; this rapidly increased as his urine diminished in quantity; he had considerable dyspnoea, which was much intensified by exertion of the slightest kind, amounting at last to orthopnœa. No ocular symptoms, except those due to age. The scrotum began to swell as the œdema extended upward, then the abdomen became œdematous, and finally the whole cutaneous surface pitted on pressure. He had Chagres fever in 1851. Had syphilis thirty years ago. Eight years ago Dr. Gross, of Philadelphia, operated on him for necrosis of the frontal bone, the scar of which is now very marked. Has been a moderate drinker.

On admission, patient is a man of large, well-built frame; the œdema on the body reaches the axillæ; skin, dry and harsh, on the arms hangs in folds, and is generally studded with an old syphilitic eruption. Tongue dry, with a lemon-colored coating in the centre. He complained of intense dyspnœa and extreme weakness. In the evening he was slightly delirious. Temperature, 101.5°. Pulse, 82, irregular in rhythm, weak, rather incompressible, and small. Respiration, 38; lungs—breath-sounds weak, with universal bronchitic râles, dulness on percussion over both bases, and total absence of fremitus. Liver small, moderate ascites. Heart, much dilated, apex-beat diffused, and impulse almost absent. It was difficult, owing to the fluid in the pleura and the cutaneous anasarca, to make out the limits of the cardiac dulness. Heart-sounds were reduplicated at the apex, with a soft systolic murmur. Ordered to be dry cupped, and a purge of calomel, gr. v.; pulv. jalapæ co., gr. xxx. The urine, for the first twenty-four hours, was ℥ xv., dark; sp. gr., 1.026; no albumen. Ordered tr. strophanthus, gtt. iv.; tr. belladonna, gtt. x.;

spts. eth. sulph. co., ʒ j.; infus. digitalis, ʒ ij., every four hours.

December 10th.—Patient feels much better; dyspnœa much diminished; œdema disappearing rapidly. Pulse, 78, regular, full, and strong. Urine, over ℥ xxx. in the twenty-four hours, still dark red; sp. gr., 1.023.

December 13th.—Much improved; dyspnœa almost entirely disappeared; œdema of scrotum gone. Pulse, 76, strong, regular, full, and more compressible. The bronchitis has subsided, and but few râles heard at the base of the lungs. Urine lighter in color, ℥ xlv. per diem; sp. gr., 1.024. Ordered tr. strophanthus, gtt. iv.; nitro-glycerine, ♏ ij. (solution, 1 p. c.); tr. belladonna, gtt. x.; spts. eth. sulph. co., ʒ j., every four hours.

December 19th.—Patient steadily improved, face no longer puffy, feels better than for six months, dyspnœa very slight. Heart much stronger in systole; pulse, regular and full; discharged at his own request.

CASE II. *Cardiac dilatation, with anasarca; bronchitis.*—G. McK——, widower, machinist, Scotch. Patient, an old soldier of uncertain age, admitted December 22d, 1887. Two months ago he had an attack of rheumatism in right knee and hip. These joints swelled up, became exquisitely tender, but not red; feet have been swollen more or less for the last sixteen months; he has passed urine only in small quantities, for the last eight months; he is troubled with occasional frontal headache; has anorexia, cardialgia, and chronic dyspepsia. On the slightest exertion he has a fluttering about his heart, with slight precordial pain; blueness of the lips and dyspnoea; also muscæ volitantes. He has a chronic bronchitis, with thick, muco-purulent expectoration, which has been troublesome for four months. Bowels much constipated, with movements only once or twice a week. He received a double inguinal hernia while in the army, in 1863, and has also a ventral hernia in the rectus abdominis muscle, between the ensiform cartilage and the umbilicus. He has been a hard drinker for over twenty-five years, and often drinks before breakfast, and on an empty stomach during the day. He has had chancre, but no secondary symptoms.

On admission, patient has extreme anæmia; conjunctiva and other mucous membranes, as well as the skin, almost white; tongue flabby, but not coated. He complains of great weakness and pain in stomach, and in right leg. He has œdema of both legs, thighs, and of the cellular tissue of the abdominal walls, with moderate ascites. Temperature, 98.5°; pulse, 80, very weak, intermittent, and irregular; respiration, 24; much cough, with fine râles. Heart, increased area of dulness, weak impulse, no murmurs. Ordered pulv. jalapæ co., gr. xl.

December 24th.—Ordered tr. strophanthus, tr. digitalis, āā ♏ iij., every three hours.

December 26th.—Pulse, 80, stronger, less irregular or intermittent; urine, ℥ xii.; sp. gr., 1.022; no albumen. Continue treatment.

December 28th.—Pulse, 76, stronger; urine, ℥ xxx.; sp. gr., 1.022.

December 30th.—Heart-impulse stronger; pulse almost wholly regular; urine, ℥ xxxvi.; sp. gr., 1.020.

January 8th.—Urine, ℥ xl.; sp. gr., 1.012.

January 15th.—Urine, ℥ xxxvi.; sp. gr., 1.023; traces of albumen. Ordered tr. digitalis, tr. strophanthus, āā ♏ iij.; sol. nitro-glycerine, ♏ ij., every three hours.

January 20th.—Patient up and about the ward, feeling very well; urine, ℥ xxxv.; sp. gr., 1.024; pulse, 70, full and regular.

CASE III. *Cardiac hypertrophy and dilatation; old pericardial adhesions; anasarca; no improvement; death.*—A. H——, American, aged forty-six, married, butcher; admitted January 20th, 1888. Last October patient had an attack of right paralysis, coming on with vertigo, dizziness, aphasia, with paralysis of right arm and leg, which lasted one week, and gradually disappeared. He had articular rheumatism twenty years ago, without, as he says, any cardiac symptoms; again, sixteen years ago, without cardiac symptoms. He has been a hard drinker, taking liquors on an empty stomach, for the last seven years. He has been troubled for a year past with palpitation, muscæ volitantes, and vertigo. Four weeks ago, after working very hard as a carver in a restaurant, he had a sharp pain come on in the precordium, with a hacking cough and dyspnœa, but he had no fever. His thighs and legs became much swollen; urine, dark and scanty. One month ago had an ulcer develop on the left cornea, with conjunctivitis. He suffers now from dyspnœa and constipation. Had gonorrhœa and a chancre three years ago, without secondary symptoms. On admission, temperature normal; pulse very small, and only every other heart impulse reaches the radials; it is very irregular and intermittent; heart-beats, about 130; respirations shallow, 38; no cyanosis; countenance and conjunctiva slightly jaundiced; orthopnœa; œdema of legs to the middle of the thighs; urine, ℥ xviii.; no albumen. Ordered tr. strophanthus, ♏ iv.; sol. nitro-glycerine, ♏ ij., every three hours.

January 21st.—Heart feeble; pulse irregular, intermittent, and rapid. He is unable to lie down without morphia and atropia. Heart hypertrophied and dilated, lying transversely on the diaphragm, mitral regurgitant murmur soft and prolonged, and also at the apex a localized double, pericardial murmur; the fifth, sixth, and seventh intercostal spaces retract during the systole, owing to old pericardial adhesions. Ordered tr. strophanthus, ♏ vj.; sol. nitro-glycerine, ♏ ij., t. i. d. Urine, ℥ xvi., lighter in color.

January 23d.—No better; urine only ℥ viii. in twenty-four hours; œdema continues. Continue treatment.

January 24th.—Ordered tr. digitalis, ♏ v.; sol. nitro-glycerine, ♏ ij.

January 26th.—Patient has been delirious last two days; slight jaundice; pulse very feeble, irregular, and intermittent; œdema of legs and thighs; heart does not respond to digitalis.

January 26th, 1 A.M.—Died.

CASE IV. *Cardiac dilatation; Bright's disease; cirrhosis of the liver; anasarca; ascites; hydrothorax; much improvement; relapse; death.*—Margaret W——, aged forty-five, Scotch, widow, cook; admitted December 14, 1887. A month ago, patient began to complain of pain in precordial region. Had palpitation and dyspnœa and a muco-purulent expectoration, which, however, was only temporary. Pain in heart often radiated to shoulder and to back, and at times was quite severe and accompanied by fluttering sensation under the left nipple. Has suffered some from headache, and at times has attacks of amblyopia, and often sees spots, black and white, before the eyes. Her urine has been very scanty and dark colored, and she would sometimes go twenty-four hours without passing any. It contained a sediment. At the time her urine gets scanty her feet swell to an immense size. She has suffered from dyspeptic symptoms for the last eighteen months; never vomits, but suffers considerably from pyrosis and gaseous eructations. She has never had any acute illness since childhood; takes whiskey regularly, sometimes to excess, often on an empty stomach. At times, when she is drinking, does not eat for several days.

On admission, patient very stout and apparently well nourished; has considerable cyanosis about the ears, neck, and lips; extreme dyspnœa, and much inclined toward somnolence; legs very œdematous; arms and face much swollen. Temperature, 98.5°; pulse, 130, small, irregular, weak, and compressible; urine dark colored, and only ℥ xi. in twenty-four hours; sp. gr., 1.028; no albumen; has incontinence of urine and involuntary movements from the bowels. Respirations, 38, very labored. Nausea, can take nothing but milk and lime-water. Examination shows hydrothorax, with ascites. Heart, increased area of dulness, with diffused and feeble apex-beat; double aortic and systolic mitral murmurs, diagnosed as secondary to the dilatation and not to valvular disease.

Ordered, December 14th, pulv. jalapæ co., gr. xl.; calomel, gr. v.

December 15th.—Ordered, tr. strophanthus, ♏ iv.; sol. nitroglyc., ♏ ij., every three hours.

December 20th.—Pulse, from 130 has gone down to 108, much stronger and regular; urine increased markedly, and, although there is still incontinence, it is not so constant. The patient is much brighter, and the somnolence lessened, though still present; her dyspnœa is much diminished.

December 24th.—Patient felt so well that she got up and sat in a chair for an hour; the heart is much stronger in systole, and more regular in force and rhythm; pulse strong, regular, and full; urine increasing.
